Abstract

The innate immune system plays a pivotal role in the primary defence against invasive fungal infection. Genetic variation in genes that regulate this response, initiated by pulmonary macrophages, may influence susceptibility to invasive aspergillosis (IA) in patients at risk. We investigated whether common polymorphisms in Toll-like receptor- (TLR) and cytokine genes involved in macrophage regulation contribute to susceptibility to IA. Forty-four allogeneic stem cell transplantation (ASCT) recipients diagnosed with probable- or proven IA according to 2008 EORTC/MSG criteria, were enrolled. The control group consisted of 64 ASCT recipients without IA. The TLR4 1063A>G single nucleotide polymorphism (SNP) was associated with IA when present in donors of ASCT recipients (OR 4.50 95%CI 1.14-17.8, p=0.02). In a multivariate analysis adjusted for occurrence of graft-versus-host-disease and duration of neutropenia, paired presence of the TLR4 1063A>G and IFNG 874T>A or TLR6 745C>T and IFNG 874T>A SNPs showed a trend towards increased susceptibility to IA (p=0.038 and 0.081 respectively). These findings point to the relevant immunological pathway involved in resistance to IA and warrant further study of the effects of TLR and cytokine polymorphisms and their interaction, which may occur on different levels of the complex biological interplay between the immunocompromised host and Aspergillus sp.
Introduction

It is incompletely understood why some hematologic transplant patients develop invasive aspergillosis (IA), a cause of considerable morbidity and mortality, while others remain unaffected [1]. Clinical risk factors for development of invasive fungal infections (IFI), have been identified, but such risks are not absolute [2, 3]. Likely, the host’s or, in case of allogeneic stem cell transplantation (ASCT), the donor’s genetic signature may influence susceptibility to acquiring manifest IA or at least affect its clinical course. In-vitro- and animal studies indicated that the innate immune system plays a pivotal role in defence against IFI, by pathogen recognition and activation of appropriate host defence mechanisms in pulmonary macrophages [4, 5]. A family of pathogen recognition receptors (PRRs), the Toll-like receptors (TLRs), mediate this process through detection of fungal components and initiation of intracellular signalling pathways that lead to a pro-inflammatory cytokine response [6-10]. Only recently, certain single nucleotide polymorphisms (SNPs) in TLR4 as well as in TLR1 and TLR6 genes were associated with occurrence of IA in ASCT recipients [11-13]. However, the response of the innate immune system relies on a complex network of components which encompasses TLRs as well as molecules of signaling pathways (e.g. MyD88 and NFκB) and subsequently secreted cytokines [14] In this respect, animal studies showed that depletion of IL-12 and IFN-γ delayed pulmonary clearance of A. fumigatus in mice [15]; moreover, a high production of IL-12 and IFN-γ had a protective effect [16]. In humans, little is known about the role of these or other cytokines in the context of innate or acquired anti-fungal defense mechanisms and only scarce data is available to validate the clinical and experimental findings so far. Hence, we aimed to investigate relevance of common genetic polymorphisms, focusing on the TLR-mediated-IL-12-IFN-γ loop to macrophage activation, with regard to susceptibility to development of IA in ASCT recipients.

Methods

Study population

The study cohort consisted of 44 patients with hematological disorders and diagnosed with either proven or probable IA following ASCT according to the revised 2008 European Organization for Research and Treatment of Cancer and Mycosis Study Group (EORTC/MSG) criteria[17]. All patients were treated at the Leiden University Medical Center, a tertiary care and teaching hospital in the Netherlands. Patients were recruited from the database of the Department of Infectious Diseases. Sixty-four patients with comparable hematological disorders but who did not develop IA, were enrolled in the control group. The ethnic background was Caucasian in both groups and all patients had undergone T-cell depleted
ASCT. Demographic and clinical characteristics as well as outcome data were collected from the hospital’s electronic database. The duration of neutropenia to the diagnosis of IA was defined as the number of consecutive days from the first day of a granulocyte count <0.5 x10⁶ cells/L (determined ±3 times weekly) to the day that microbiological evidence of IA was first obtained. The study was endorsed by the local medical ethics committee. No standard prophylaxis active against Aspergillus sp. was used. Clinical characteristics per group are as summarized in table 1.

Polymorphisms and genotyping

Polymorphisms were considered eligible for study if the SNP was previously reported to be associated with the occurrence of IA and had an expected allele frequency of ≥5% in the population. With regard to the focus of interest as pointed out in the introduction, two SNPs...
Chapter 7

Influence of polymorphisms in innate immunity genes on susceptibility to invasive aspergillosis

Blood- or bone marrow samples were used to isolate DNA. Genotyping of polymorphisms was performed by use of a Mass Array platform according to the manufacturer’s protocols (Sequenom, San Diego, USA). Multiplex assays were designed using Assay designer software (Sequenom). In brief, after PCR on 2.5 ng of DNA a primer extension reaction was performed to introduce mass-differences between alleles and, after removing salts by adding a resin, ~15 nl of the product was spotted onto a target chip with 384 patches containing matrix. Mass differences were detected using a Bruker Autoflex MALDI-TOF mass spectrometer and genotypes were assigned real-time using Typer 3.1 software (Sequenom). As quality control, 10% of samples were genotyped in duplo; no inconsistencies were observed. Primer sequences are available upon request.

Statistical analysis

Genotype- and allele frequencies were calculated and compared between groups by Pearson-chi-square and Fisher’s exact tests. Odds ratio (OR) and 95% confidence interval (95%CI) were calculated for the presence (homozygous or heterozygous) or absence (homozygous wild type allele) of the selected SNPs. All polymorphisms were tested for the Hardy-Weinberg
equilibrium. Due to the possibility that development of IA was influenced by SNPs in the donor DNA, genotype and allele frequencies were also compared between donors of the patients with IA and donors of control patients. Because of expected redundancy and complexity in the pathway to granulocyte and macrophage activation, the relevance of the combined presence of the selected polymorphisms was assessed in a contingency table. The influence of a selected SNP on the course of disease (i.e., duration of neutropenia to day of diagnosis or time from IA diagnosis to death) was assessed by Kaplan-Meier analysis (log rank-test). The SPSS version 17.0 statistical software package for Windows was used for all calculations.

**Results**

A total of 10 candidate polymorphisms, all acting within the type-1 cytokine loop to macrophage activation, were selected for analysis: five SNPs in three different TLR genes (-1,-4 and -6) and five SNPs in the IL10, IL12B and IFNG genes (table 2). Distribution of genotypes was consistent with the Hardy-Weinberg equilibrium except for the IL12B SNP. The TLR4 1063A>G and TLR4 1363C>T SNPs were in strong linkage disequilibrium, i.e. when the 1063A>G SNP was found, the 1363C>T was almost always also present. No significant difference in genotype or allele frequencies was found between patients with IA and control patients (data not shown). When comparing donor genotype and allele frequencies, the TLR4 1363C>T and TLR4 1063A>G SNPs were more frequently present in donors of patients with IA (table 3).

The donor DNA contained the TLR4 1063A>G SNP in 9 of the 43 case patients (21%) and in 3 (6%) of the 54 control patients successfully genotyped for this polymorphism (OR 4.50 95%CI 1.14-17.8, p=0.02). Following multivariate correction for GVHD and duration of neutropenia the adjusted OR was 3.76 (95% CI 0.90-15.8, p=0.07). In addition, the allele frequency of the IFNG 874T>A polymorphism showed a trend towards association with IA when present in donors of patients with IA (OR 1.60 95%CI 0.91-2.79, p=0.10).

Since our hypothesis was that susceptibility to IA by genetic mutations could be influenced by the interplay of both TLR and cytokine gene mutations, relevance of the combined presence of the selected polymorphisms was assessed in a contingency table (i.e. association of occurrence of IA with the presence of at least one minor allele in both genes in the interaction term). With respect to this analysis no significant associations with IA were found in the comparison of patients with IA versus control patients. However, a similar analysis performed for the genotypes of the donor samples revealed that paired combinations of the TLR4 1063A>G, TLR6 745C>T, or IFNG 874T>A SNPs correlated with occurrence of IA in the recipient (table 4). After multivariate adjustment for GVHD and neutropenia only the association between the TLR4 1063A>G and IFNG 874T>A combination and IA remained statistically significant (p=0.038). When using a forward conditional logistic regression model for assessment of
Influence of polymorphisms in innate immunity genes on susceptibility to invasive aspergillosis

The strength of the association of individual or paired polymorphisms with IA, incorporating both the single presence of the minor SNP in the TLR4, TLR6 and IFNG genes as well as their paired combinations, showed that the TLR4 1063A>G / IFNG 874T>A combination was most strongly linked with IA (p=0.033).

Kaplan-Meier analysis did not reveal significant differences in time to development of IA between recipients or their donors bearing either only the wild-type or variant allele. There was no difference in survival (time to death following diagnosis of IA) consequent to having one or two minor alleles of the selected SNPs in either recipients or their donors.

Discussion

We found that in this study cohort the TLR4 1063A>G polymorphism was associated with increased susceptibility to IA, when present in the donors DNA of ASCT recipients (alone or in combination with TLR6 745C>T or IFNG 874T>A SNPs). None of the cytokine polymorphisms alone was linked with occurrence of IA. The results of our investigations concur with the study by Bochud et al in which the 1363C>T and 1063A>G polymorphisms in the TLR4 gene were demonstrated to be associated with IA when present in donors of ASCT recipients.[11] In contrast, an increased risk for IA was previously reported for the 1063A>G SNP if present in the recipients DNA but not in the donor DNA [12]. The association between IA and the TLR1 239G>C SNP or between IA and the combination of the TLR1 743A>G and TLR6 745C>T SNPs as reported in a smaller study by Kesh et al. [13], was not confirmed by our data.

The IFNG 874T>A SNP was found to potentially add up to the risk conferred by two of the TLR polymorphisms. Although carriers of this genetic variation produce suboptimal levels of IFN-γ, putting them at increased risk for perhaps manifest tuberculosis, the isolated presence in either donor or recipient did not increase the risk for IA. Remarkably, SNPs that affect the production of IL-10, one of the most important broad-acting negative modulators of the TLR to IL-12 and IFN-γ macrophage-activating pathway, did not influence susceptibility to IA. Absence of IL-10 was demonstrated to cause increased survival of susceptible mice when exposed to Aspergillus fumigatus and in a prospective clinical study a tendency towards protection against IA was detected when the -1082 A/A-genotype was present [18].

As compared to other risk factors, the absolute risk conferred by relevant SNPs in PRR- and cytokine genes is likely to be limited, given the fact that individuals carrying these SNPs do not develop IA unless another immune deficiency is present. Moreover, our data indicate that even in hosts most at risk, the ability to maintain a response to IA is largely unaffected by the studied SNPs, underscoring the already expected redundancy inherent to the human antifungal defense [19]. Likely, specific patterns of genetic polymorphisms rather than a single genetic variation in TLRs or subsequent cytokine pathways that activate macrophages may be associated with IA in patients at risk. The observation of the association between the TLR4 1063A>G plus IFNG 874T>A SNP combination and IA fits such a hypothesis. However, probable associations of IA with conditional combinations of mutations may also attest to the complex immuno-pathogenesis of invasive aspergillosis. As a consequence of neutropenia, the role of key components within the innate immune response (e.g. lung macrophages phagocytosing and eliminating Aspergillus conidia) could be more prominent in the remaining defense against invasive fungal infection and thus facilitate linkage to TLR- in combination with cytokine SNPs. Assuming that the studied SNPs have an effect on the functioning of the innate immune system, different SNPs may also be working at different time points to modulate resistance to IA and eventually constitute the hosts genetic signature of susceptibility.
The study has limitations, e.g. due to a retrospective design and size of the study cohort. However, two studies that explored the role of TLR SNPs and risk for IA included a comparable or even smaller number of patients [12, 13]. Of note, rather than performing a genome-wide analysis, or testing a random collection of immune genes, we chose to investigate the association of IA with pre-set polymorphisms in candidate genes involved in type-1 cytokine loop to macrophage activation. This ameliorates implications with regard to the concept of multiple testing, but by some a significance level of 0.05 may be regarded too liberal. Currently an ongoing discussion about the necessity of p-value adjustment in exploratory epidemiological studies still evolves and with all relevant data reported, final judgment is left to the reader [20, 21]. Furthermore, due to the rapidly evolving research field, producing newly found candidate SNPs like the Dectin-1 Y238X polymorphism, investigations can hardly ever be complete [22].

The overall impact of the reported TLR4 1063A>G and IFNG 874T>A SNPs on the risk of IA should be interpreted with care. Relative risk associations of genetic variations in the case of IA do not stand alone but likely are influenced again by other components in the host’s defense. As discussed above, the observations of this study may be accounted for by both a system of redundancy in the innate immune system as well as by the complex biological interaction between the immunocompromised host and the invading fungus. At present, the findings do not extent to the bedside yet, e.g., by providing guidance for individualized prophylaxis or early intervention. However, by further unravelling the interplay between the innate host defense and Aspergillus sp. through experimental and clinical investigations, increased comprehension of the underlying immuno-pathogenetic processes may, in time, translate into insights directly relevant to clinical practice.
