ABSTRACT

Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis is the commonest cause of rapidly progressive glomerulonephritis worldwide and the renal biopsy is the gold standard for establishing the diagnosis. While the prognostic value of the renal biopsy in ANCA-associated glomerulonephritis is well recognized, there is no international consensus for its pathologic classification.

We present such a pathologic classification developed by an international working group of renal pathologists. Our classification proposes four general categories of lesions: focal, crescentic, mixed, and sclerotic.

To determine if these lesions have predictive value for renal outcome, we performed a validation study on 100 biopsies from patients with clinically and histologically confirmed ANCA-associated glomerulonephritis. Two independent pathologists, blinded to patient data scored all biopsies according to a standardized protocol. Results show that the proposed classification system is indeed of prognostic value for 1- and 5-year renal outcome.

We believe this pathologic classification will aid in the prognostication of patients at the time of diagnosis and facilitate uniform reporting between centers. This classification at some point might also provide means to guide therapy.
BACKGROUND

The antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides, particularly Wegener’s granulomatosis (WG) and microscopic polyangiitis (MPA), often affect the kidneys, and renal involvement is an important factor with respect to patient morbidity and mortality. Although rapidly progressive renal failure in patients who are seropositive for ANCA by indirect immunofluorescence or ELISA is suggestive of ANCA-associated glomerulonephritis, the morphologic changes in the renal biopsy are still the gold standard for establishing a diagnosis.

ANCA-associated glomerulonephritis is characterized on immunofluorescence microscopy by little or no glomerular staining for immunoglobulins or complement, the so-called pauci-immune staining pattern. By electron microscopy, subendothelial edema, microthrombosis and degranulation of neutrophils are present, but immune deposits are absent. Light microscopy shows necrotizing and crescentic glomerulonephritis. Until now, there has been no histopathologic classification of ANCA-associated glomerulonephritis, although there is a clinical need to distinguish the levels of severity.

A large number of clinicopathologic studies investigating diagnostic and follow-up renal biopsies demonstrate that specific pathologic lesions, or the absence thereof, are important predictors for renal outcome in ANCA-associated vasculitis, and that the combination of baseline glomerular filtration rate (GFR) and renal histology is a better predictor of renal outcome than baseline GFR alone. One consistent finding in these studies is the relationship between a high percentage of normal glomeruli, not affected by the disease process, and favorable renal outcome. In fact, the percentage of normal glomeruli is a strong predictor, possibly the best histologic predictor, of short- or long-term renal outcome. In addition to the relation of normal glomeruli to outcome, a high percentage of globally sclerotic glomeruli has been related to adverse renal outcome repeatedly. The percentage of active crescentic lesions, in particular cellular crescents, is related to recovery of renal function independent of baseline GFR. Conversely, the percentage of fibrous crescents adversely affects long-term renal outcome.
Apart from glomerular lesions, acute and chronic tubulointerstitial lesions have been associated with renal outcome, and tubular atrophy is an especially important risk factor for impaired renal function during follow-up. The relationship of vascular lesions to renal outcome has been reported less frequently, although arteriosclerosis in the initial biopsy is identified as a risk factor for chronic dialysis.

While a standardized scoring protocol for renal biopsies of patients with ANCA-associated vasculitis, with good reproducibility, has been developed previously, a histopathologic classification is still lacking. Considering the substantial diagnostic and prognostic value of the renal biopsy in ANCA-associated glomerulonephritis, we propose a histopathologic classification based on glomerular pathology. Most histologic classifications of renal diseases have been primarily based on expert experience, our proposed classification, however, is also validated with patient data.

CLASSIFICATION PROPOSAL FOR ANCA-ASSOCIATED GLOMERULONEPHRITIS

The proposed classification is based on glomerular pathology as assessed by light microscopy. For classification purposes, adequacy of tissue specimens and histopathologic techniques is essential. A minimum of 10 whole glomeruli is considered adequate. Hematoxylin and eosin (H&E), methenamine silver and Periodic acid-Schiff (PAS) stainings are minimally required for examining renal histopathology. A Masson trichrome staining, or one of its variants, can be helpful to visualize fibrinoid necrosis, acute tubular necrosis, and interstitial fibrosis but is not necessary for our proposed classification schema.

The classification is built around four general categories: focal, crescentic, sclerotic, and mixed. The categories labeled focal, crescentic, and sclerotic are based on the predominance of normal glomeruli, cellular crescents, or globally sclerotic glomeruli, respectively. The mixed category represents a heterogeneous glomerular phenotype wherein no glomerular feature predominates. Definitions of histologic variables used in our classification are reported in Table 1 and the classification schema is depicted in Table 2.
Table 1. Definitions

<table>
<thead>
<tr>
<th>Total number of glomeruli</th>
<th>The maximum number of glomeruli in one of the sections excluding incomplete glomeruli on the edge</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal glomeruli</td>
<td>Glomeruli without vasculitic lesions or global sclerosis. Normal glomeruli may show subtle changes as a result of ischemia or a minimum number of inflammatory cells (fewer than four neutrophils, lymphocytes, or monocytes)</td>
</tr>
</tbody>
</table>

Exclusion criteria are
- synechiae
- local/segmental glomerulosclerosis
- extensive ischemic changes (splitting of Bowman’s capsule, wrinkling of the GBM)
- any other lesion unrelated to vasculitis (e.g. amyloid, tram tracking)

Crescents
- cellular: Purely cellular lesions or with cellular components
- fibrous: Fibrotic (sclerotic) lesions with fibroblasts filling Bowman’s space

Global glomerulosclerosis >80% of the glomerulus sclerosed

Inter- and intraobserver agreement on these scores has been described previously.16

aPauci-immune staining pattern on immunofluorescence microscopy (IM) and ≥ 1 glomerulus with necrotizing or crescentic glomerulonephritis on light microscopy (LM) are required for inclusion in all four classes. See Figure 1 for hierarchical structure.

The biopsies in the focal category contain ≥ 50% normal glomeruli that are not affected by the disease process. The crescentic category contains biopsies with ≥ 50% of glomeruli with cellular crescents. Biopsies from the sclerotic category contain ≥ 50% of glomeruli with global sclerosis. All remaining biopsies (Figure 1) are, per definition, not characterized by one predominant glomerular phenotype and form the mixed category. These latter biopsies will have all above-mentioned glomerular features to varying degrees.
The typical description of immunofluorescence findings in ANCA-associated glomerulonephritis is that of a so-called pauci-immune pattern, firstly described by Jennette, and defined as less than 2+ glomerular immunostaining for immunoglobulins. A coarse granular staining with positivity for mesangial IgA has been described in a small number of patients with ANCA-associated glomerulonephritis. This staining pattern is not an exclusion criterion for the current classification.

It is known that in approximately 10% of patients with a clinical picture characteristic of ANCA-associated vasculitis as well as pauci-immune crescentic glomerulonephritis in their biopsies, serological ANCA tests are negative. These biopsies can be classified using the proposed schema. Currently, our classification does not take into account patients with comorbid diseases or overlap syndromes, such as ANCA-associated glomerulonephritis in combination with anti-glomerular basement membrane (GBM) nephritis. Patients who are double positive serologically for anti-GBM antibodies and ANCA (usually MPO-
ANCA) and whose biopsies show distinct, intense linear staining for IgG, are known to have a worse renal outcome which is defined by the anti-GBM nephritis component.\textsuperscript{23,24} Biopsies of these patients should not be classified according to the system proposed here. This exclusion criterion of comorbid disease also applies for all other renal diseases. Although infrequently found, cases of ANCA-associated glomerulonephritis have also been described in combination with diabetic nephropathy, lupus nephritis or membranous glomerulonephropathy.\textsuperscript{25-27}

The proposed classification system hinges on the recognition of normal glomeruli, glomeruli with cellular crescent formation, and glomeruli with global glomerulosclerosis. Straightforward as this may seem, interobserver disagreement may arise for recognition of these features in individual glomeruli. We refer to Figure 2 for typical examples of glomeruli that belong or do not belong to the various categories of classification. Furthermore, we now offer explicit guidelines to distinguish these features in more detail.

**Normal glomeruli**

According to the definition provided in Table 1, a normal glomerulus does not exhibit features of vasculitic lesions or global glomerulosclerosis. It also should not show intracapillary proliferation, meaning no extensive endothelial swelling or proliferation in more than one capillary loop, or more than four intracapillary inflammatory cells (neutrophils, lymphocytes, or monocytes) in all of the glomerular capillary bed. Normal glomeruli should not have synechiae or any local or segmental glomerulosclerosis. Normal glomeruli may show subtle signs of ischemia: slight collapse of the tuft, focal splitting of Bowman’s capsule, or focal wrinkling of the GBM. Ischemia may lead to a more prominent appearance of the parietal epithelium of Bowman’s capsule. As long as the epithelium remains as a monolayer and does not show signs of atypia or influx of inflammatory cells, these changes could be accepted within the scope of ischemia, and not be regarded as extracapillary proliferation. We refer to Figure 2 showing examples of subtle versus overt changes due to ischemia, giving guidance as to which are still acceptable in the context of a normal glomerulus.
Figure 2. Typical examples of glomerular lesions in each of the four categories. (A through C) Normal glomeruli, allowing for fewer than four leukocytes in the capillary tuft (B) or mild ischemic changes such as wrinkling of the GBM (C). Cellular crescents contain > 10% of cellular components. Whether crescents are segmental or circumferential is irrelevant for the classification schema. (D through G) Examples of cellular crescents. The amount of fibrinoid necrosis is irrelevant. (H through J) If > 90% of a crescent consists of extracellular matrix, then the term fibrous crescent is used. (K) Global glomerulosclerosis refers to sclerotic changes in the glomerulus composing > 80% of the tuft. Global glomerulosclerosis excludes the designation of any other glomerular lesion.
**Crescents**

Cellular crescents are defined as either purely or partially cellular crescents in which fibrous components are allowed. They are distinct from fibrous crescents which are defined as purely fibrotic lesions, in which a cellular component is virtually absent. If > 90% of a crescent consists of extracellular matrix, the term fibrous crescent is used. As long as the crescent contains cellular components > 10%, it is regarded as a cellular crescent, irrespective of whether it is segmental or circumferential, or whether it contains other components such as fibrin, or is accompanied by a periglomerular granulomatous reaction or by breaks in Bowman’s capsule. Whether or not the glomerulus has a fibrinoid necrotic lesion is not regarded relevant for classification purposes. Segmental crescents show extracapillary proliferation in < 50% of the circumference of Bowman’s space, while circumferential crescents show extracapillary proliferation in > 50% of Bowman’s space.

**Global glomerulosclerosis**

We define global glomerulosclerosis as sclerotic changes in the glomerulus comprising more than 80% of the tuft. It is irrelevant whether the global glomerulosclerosis is attributable to ANCA-associated glomerulonephritis or not. In our classification system, global glomerulosclerosis excludes the designation of any other glomerular lesion.

**Recommendations for reporting of tubulointerstitial and vascular lesions**

The current proposal for ANCA-associated glomerulonephritis is based purely on the presence of glomerular lesions; however tubulointerstitial lesions have also been reported to be of prognostic value in ANCA-associated vasculitis. For guidelines on how to systematically report on tubulointerstitial and vascular lesions we refer to the scoring form which was devised previously for the standardized evaluation of biopsies with ANCA-associated glomerulonephritis.

Unless the findings are quite remarkable, tubulointerstitial and vascular lesions need not be mentioned in the final diagnosis. Examples of remarkable findings are: a dominance of any cell type in the infiltrate (plasma cells or eosinophils), a high number of interstitial granulomas, or extensive arteriosclerosis. Some of these findings may have clinical consequences or be of importance in the differential diagnosis of other diseases, such as drug hypersensitivity, infection, or cardiovascular disease.
VALIDATION STUDY FOR THE CLASSIFICATION

Concise methods

Data

Renal histology data from patients entered into two randomized controlled trials (CYCAZAREM and MEPEX) conducted by the European Vasculitis Study Group between March 1995 and September 2002 were pooled. Trial outcomes and clinico-pathologic studies from these trials were previously published. For the current study, patients were included who had been followed up for at least 12 months (including patients who died within the first 12 months, but excluding patients who were lost to follow-up). Five year follow-up was available for a subset of patients, and reported on. Adequacy of tissue specimens and histopathologic techniques are mandatory for a reliable classification. For this validation exercise we included biopsies with a minimum of 10 whole glomeruli. H&E, silver, PAS and Masson trichrome stainings were available for evaluation. All biopsies were scored independently by two pathologists, who were blinded to patient data, from a group of five pathologists [FF, IMB, JAB, LHN, RW], according to a previously standardized protocol; discrepancies were resolved during consensus meetings. Patients with Churg-Strauss Syndrome were not included in this study, and this classification proposal is not validated for these patients.

Glomerular filtration rates were estimated (eGFR) using the four-variable Modification of Diet in Renal Disease equation (MDRD). To evaluate an independent predictive effect of the classification on eGFR at 1- and 5-year follow-up, we corrected for the eGFR at baseline. The corrected eGFR at a timepoint was defined as the difference between the observed eGFR at that timepoint and its linear prediction on the basis of baseline eGFR. In addition to renal function at different follow-up times, renal survival, as defined as time to end stage renal failure, was assessed.

Statistics

Chi square, oneway ANOVA, and multiple linear regression analyses were performed as appropriate. Renal survival was assessed using the Kaplan-Meier method. Differences between categories were assessed using the log-rank test. Hazard ratios were acquired using Cox proportional hazards regression.
A p-value < 0.05 was considered significant.

**Results**

**Patients and data**
Following the stringent inclusion criteria described in the methods section, a total of 100 patients with at least 1 year follow-up and adequate renal histology were included in a validation study. These patients came from 32 centers in 9 European countries. Median age at baseline was 62.6 years (range 20.4-80.7). The male to female ratio was 54:46. All 100 patients had a clinicopathologic diagnosis of WG (n = 39) or MPA (n = 61) with pauci-immune crescentic glomerulonephritis. ANCA test results by indirect immunofluorescence or ELISA were available for 97% of patients (PR3-ANCA n = 45, MPO-ANCA n = 47, negative ANCA test n = 2, missing n = 3). Thirty-five patients reached end stage renal disease (ESRD), and mean time to reach ESRD was just over 1 year from baseline. The median number of glomeruli per biopsy was 14.8 (range 10-49).

**Classifying 100 renal biopsies**
Following the proposed classification and flow chart (*Table 2* and *Figure 1*), 13 biopsies were classified as sclerotic ANCA-associated glomerulonephritis (≥ 50% globally sclerotic glomeruli). Of the 87 biopsies left, 16 were classified as focal (≥ 50% normal glomeruli). After taking out the biopsies that were classified as sclerotic or focal, 71 were left for study. Fifty-five of these biopsies demonstrated ≥ 50% of glomeruli with cellular crescents and these biopsies were classified as crescentic. No biopsy showed > 50% pure fibrous crescents. The remaining 16 biopsies could not be classified into either a predominantly sclerotic, focal, or crescentic phenotype and were classified as a mixed phenotype. None of the biopsies in this cohort exhibited 50% globally sclerotic glomeruli together with 50% normal glomeruli or glomeruli with cellular crescents. Likewise, no biopsies exhibited 50% normal glomeruli and 50% crescentic glomeruli.

The 16 biopsies that were classified as demonstrating a mixed phenotype had on average ~27% globally sclerotic glomeruli, ~21% normal glomeruli, and ~32% glomeruli with cellular crescents. Approximately 15% of glomeruli in these biopsies exhibited purely fibrous crescents and the remaining 5% of glomeruli exhibited either local/segmental glomerulosclerosis or ischemia.
Categories in relation to clinical presentation and renal outcome

As depicted in Table 3 and Figure 3, the renal biopsy categories were correlated to the degree of renal function at presentation and at 1- and 5-year follow-up (all p ≤ 0.001), with the sequence of category (focal, crescentic, mixed, and sclerotic) corresponding to the order of severity of renal function loss.

In multiple linear regression analyses investigating independent predictors for eGFR at 1 and 5 years, and taking into account patient age, treatment limb, baseline eGFR and the classification system, baseline eGFR and renal biopsy category were the only independent predictors for eGFR at both follow-up events, as depicted in Table 4. Adjusted $R^2$ values for the models at 1 and 5 years are 0.61 and 0.49 respectively, indicating that these models account for considerable percentages of the variance in eGFR at these timepoints.

Regarding the hard endpoint of development of ESRD, as depicted in Figure 4, the absolute number of events was limited. Renal survival data were available for 82/100 patients. A total of 25 cases developed ESRD during the follow-up period. ESRD de-

*Corrected for entry eGFR.
veloped in 1/14 patients with focal, in 11/45 patients with crescentic, in 6/13 patients with mixed, and in 7/10 patients with sclerotic ANCA-associated vasculitis. The data show that the percentage of patients who developed ESRD increases with ascending category (p = 0.003). A multiple Cox regression analysis, including patient age, treatment, baseline eGFR and the classification, demonstrates that patients who present with crescentic ANCA-associated glomerulonephritis are at decreased risk of developing ESRD compared with patients who present with sclerotic ANCA-associated glomerulonephritis (HR 0.176, 95% CI 0.057-0.574, p = 0.003).

Figure 3. The histologic categories are strongly and independently correlated with renal function at baseline and during follow-up, with the phenotypical order of categories (focal, crescentic, mixed, and sclerotic) corresponding to the order of severity of renal function impairment. (A) Baseline renal function (mean ± 95% confidence interval) is depicted according to histologic class. (B through D) Mean ± 95% confidence interval renal function values for the four classes at 1 year of follow-up are depicted uncorrected for baseline eGFR (B) and corrected for baseline eGFR (C); the same applies for renal function values at 5 years of follow-up (D and E).
Investigating renal outcome by looking at renal function during follow-up does not take into account patients who have died, and in survival analyses these patients are censored. We have taken the Kidney Disease Outcomes Quality Initiative (KDOQI) classification of chronic kidney disease stages as an example to describe different categories of renal outcome at 1 year, primarily based on renal function (ml/min/1.73 m²). The following four classes are considered: eGFR 60+, eGFR 15-59, eGFR < 15 or on dialysis, or death within the first year. Results of this exercise are depicted in Table 5 and illustrate that patients with sclerotic ANCA-associated glomerulonephritis not only have decreased chances of renal survival, but are at a higher risk of death as well.

Adjusted R² model eGFR at 1 year = 0.61; adjusted R² model eGFR at 5 years = 0.49.

Figure 4. Renal survival (no development of end stage renal failure) is depicted according to the four histologic categories. Renal survival at 1 year was 93% for patients whose renal biopsies were classified as focal at the time of diagnosis, 84% for patients whose biopsies were classified as crescentic, 69% for patients whose biopsies were classified as mixed, and 50% for patients whose biopsies were classified as sclerotic. Renal survival percentages at 5 years were 93% (focal class), 76% (crescentic class), 61% (mixed category), and 50% (sclerotic category). In the sclerotic category, renal survival at 7 years was only 25%.
Adding tubulointerstitial parameters to the classification system

To assess the contribution of tubulointerstitial parameters to the classification system, we investigated the influence on the classification of either a combined score of fibrosis and tubular atrophy, or individual scores of fibrosis, tubular atrophy, and intraepithelial infiltrates. Although, in general, a slight dichotomy could be seen within the four glomerular classes, wherein patients with more extensive tubulointerstitial damage had worse renal outcome, the data were not convincing enough to adjust the classification system accordingly for any of the tubulointerstitial parameters. Particularly, adjusted $R^2$ values obtained for the models taking into account the glomerular classification system as well as tubulointerstitial parameters and renal function at 1 and 5 years, did not differ from the adjusted $R^2$ values for the model taking into account glomerular pathology only (data not shown), indicating that the model including tubulointerstitial parameters did not account for a greater percentage of variance in eGFR at follow-up. Therefore, including tubulointerstitial parameters in the classification system is unnecessary and only increases its complexity.

DISCUSSION OF THIS CLASSIFICATION

ANCA-associated vasculitis is the most frequent cause of rapidly progressive glomerulonephritis worldwide, and the renal biopsy is the gold standard for establishing the diagnosis of ANCA-associated glomerulonephritis.\textsuperscript{29,30} The diagnostic and prognostic value of the renal biopsy in ANCA-associated vasculitis is widely known. We present here a proposal for a pathologic classification for ANCA-associated glomerulonephritis. The proposed classification schema has been developed by an international working group of renal pathologists and we report its validation on a set of 100 renal biopsies that were scored in a standardized manner.

$eGFR =$ estimated glomerular filtration rate.
The classification system is composed of four categories. The focal category contains biopsies wherein ≥ 50% of glomeruli are not yet affected by the disease. In the crescentic category, over half of the glomeruli have cellular crescents. The mixed category involves biopsies in which a combination of normal, crescentic, and sclerotic glomeruli are present, all occurring in less than 50% of glomeruli. Forming the sclerotic category are those biopsies characterized by ≥ 50% globally sclerotic glomeruli.

Our validation study shows that the phenotypical order of the classes corresponds to the order of severity of renal function impairment during follow-up. Patients with focal ANCA-associated glomerulonephritis present with relatively preserved renal function and have a relatively favorable renal outcome. Patients with crescentic ANCA-associated glomerulonephritis present with highly active renal disease and severely reduced renal function, but stand a good chance for renal function recovery. Patients with a mixed phenotype have an intermediate outcome profile. Patients with sclerotic ANCA-associated glomerulonephritis at the time of biopsy run the highest risk of not recovering renal function, and also have a higher risk of death within the first year after diagnosis.

This classification proved practical during an initial validation exercise. None of the 100 biopsies exhibited 50% globally sclerotic glomeruli together with 50% normal glomeruli or glomeruli with cellular crescents. Likewise, no biopsies were encountered that exhibited 50% normal glomeruli and 50% crescentic glomeruli. This indicates, in this cohort, that each biopsy clearly has one predominant glomerular feature or demonstrates a mixed phenotype. No biopsy had an overlap between categories. Additional validation cohorts will be required to confirm these conclusions. In cases in which exactly 50% of glomeruli are consistent with one feature, and 50% with another feature, the flow chart (Figure 1) will be helpful in making the final decision.

The limitations of this study reflect the problems encountered when studying relatively rare diseases. Material for the validation study came from various centers where it was processed in comparable but not exactly identical ways. Although this was an international study, all patients were seen in European centers only. The interobserver variation for the histopathologic parameters on which the classification was based was previously established, and consensus was reached for each parameter during
We encourage further validation of this classification for ANCA-associated glomerulonephritis in different cohorts throughout the world, and hopefully this will lead to classification refinements. This classification will be of aid in the prognostication of patients at the time of diagnosis, and will facilitate uniform reporting between centers.
