Accepted for publication in Obesity
ABSTRACT

Objective: The scavenger receptor CD36 facilitates the cellular uptake of long chain fatty acids. Since CD36-deficiency attenuates the development of high fat diet (HFD)-induced obesity, we set out to characterize the role of CD36-deficiency in preadipocyte recruitment and adipocyte function.

Design and methods: Fat cell size and number were determined in gonadal, visceral and subcutaneous adipose tissue of CD36−/− and WT mice after six weeks on HFD. Basal lipolysis and insulin-inhibited lipolysis were investigated in gonadal adipose tissue.

Results: CD36−/− mice showed a reduction in adipocyte size in all fat pads. Gonadal adipose tissue also showed a lower total number of adipocytes due to a lower number of very small adipocytes (diameter <50 µm). This was accompanied by an increased pool of preadipocytes which suggests that CD36-deficiency reduces the capacity of preadipocytes to become adipocytes. Regarding lipolysis, in adipose tissue from CD36−/− mice cAMP levels were increased and both basal and 8-bromo-cAMP stimulated lipolysis were higher. However, insulin-mediated inhibition of lipolysis was more potent in CD36−/− mice.

Conclusions: These results indicate that during fat depot expansion, CD36-deficiency negatively affects preadipocyte recruitment and that in mature adipocytes, CD36-deficiency is associated with increased basal lipolysis and insulin responsiveness.
Obesity, and in particular abdominal obesity, is associated with several metabolic abnormalities such as insulin resistance and hypertriglyceridemia, which increase the risk of developing type 2 diabetes and eventually cardiovascular morbidity and mortality. Obesity is caused by a chronic positive energy balance that increases the storage of triglycerides (TG) in adipose tissue. This storage of energy is partly regulated by fatty acid (FA) transporter proteins in adipocytes, which facilitate the cellular entry of lipoprotein derived FA. One of these FA transporters is CD36, a 88 kDa glycoprotein (reviewed in) that primarily facilitates the transport of long chain FA. The role of CD36 in white adipose tissue (WAT) is illustrated by diminished uptake of the FA analogs BMIPP and IPPA in adipose tissue of CD36-deficient (CD36−/−) mice fed a chow diet. Other studies have demonstrated that CD36-deficiency protects against obesity induced by a high fat diet (HFD) and development of cardiometabolic problems.

Since CD36-deficiency attenuates the development of HFD-induced obesity, we were interested in the role of CD36 in adipocyte development and function. We investigated adipocyte cell size and number in various adipose tissue depots to determine whether CD36-deficiency affects adipocyte hypertrophia (i.e adipocyte growth) and/or hyperplasia (i.e. recruitment of new adipocytes), as both these parameters determine the expansion capacity of adipose tissue. Moreover, we determined the intra cellular lipid accumulation of isolated preadipocytes of CD36−/− versus wild-type (WT) mice in vitro after incubation in adipogenic media. In addition, lipolysis rate of isolated mature adipocytes of CD36-deficient mice versus WT mice was determined, since adipocyte volume is not only determined by uptake of FA which lead to TG storage, but also by the level of FA release during the process of adipocyte lipolysis. Taken together, we aimed to investigate the role of CD36 in adipocyte development and function, since CD36 is involved in development of diet-induced obesity. The current study shows that CD36 affects both adipocyte recruitment and lipolysis.

2.2 MATERIALS AND METHODS

Animals
The generation of CD36−/− mice has been described previously. For this study, CD36−/− mice were crossed back eight times to the C57Bl/6J background. CD36−/− mice were bred at the Leiden University Medical Center, Leiden, The Netherlands. WT control mice (C57Bl/6J background) were purchased from Charles River (Maastricht, The Netherlands). The mice used in experiments were males, housed under standard conditions with free access to water and food. Mice were fed a HFD (45% energy derived from lard fat; D12451, Research Diet Services, Wijk bij Duurstede, The Netherlands) when they were 12 weeks of age to...
induce obesity. Body weight was measured regularly. All experiments were approved by the animal ethics committee of Leiden University Medical Center.

**Body composition**

After 11 weeks of HFD feeding body composition was determined in overnight fasted mice using dual energy X-ray absorptiometry (DEXA) (Norland Stratec Medizintechnik GmbH, Birkenfeld, Germany).

**Generation of TG-rich emulsion particles**

VLDL-like TG-rich emulsion particles were prepared and characterized as described previously. Lipids (100 mg) at a weight ratio of triolein: egg yolk phosphatidylcholine: lysophosphatidylcholine: cholesterol of 70: 22.7: 2.3: 3.0: 2.0, supplemented with 100 µCi of glycerol tri[9,10(n)-3H]oleate ([3H]TO) (GE Healthcare, Little Chalfont, UK) were sonicated at 10 µm output using a Soniprep 150 (MSE Scientific Instruments, Crawley, UK). Density gradient ultracentrifugation was used to obtain 80 nm-sized emulsion particles, which were used for subsequent experiments. TG content of the emulsions was measured using a commercially available kit (Roche Molecular Biochemicals, Indianapolis, IN). Emulsions were stored at 4°C under argon and used within 7 days.

**In vivo clearance of TG-rich emulsion particles**

To study the *in vivo* clearance of the VLDL-like emulsion particles, mice were fed a HFD for 13 weeks. Mice were fasted 4 h (from 8.00 am to 12.00 pm) prior to the start of the experiment and anesthetized by intraperitoneal injection of acepromazine (6.25 mg/kg Neurotranq, Alfasan International BV, Weesp, The Netherlands), midazolam (6.25 mg/kg Dormicum, Roche Diagnostics, Mijdrecht, The Netherlands), and fentanyl (0.31 mg/kg Janssen Pharmaceuticals, Tilburg, The Netherlands). Subsequently, mice were injected (t=0) intravenously with 200 µL of [3H]TO-labeled emulsion particles at a dose of 1 mg of TG per mouse. Blood samples were taken from the tail at 2, 5, 10, 20 and 30 minutes after injection and plasma 3H-activity was counted. Plasma volumes in ml were calculated as 0.04706 x body weight (g) as determined from 125I-BSA clearance studies as described previously. After taking the last blood sample, the liver, heart, spleen, quadriceps, brown adipose tissue and white adipose tissue (*i.e.* gonadal, visceral and subcutaneous) were collected. Organs were dissolved overnight at 60°C in Tissue Solubilizer (Amersham Biosciences, Rosendaal, The Netherlands) and 3H-activity was counted. Uptake of [3H]TO-derived radioactivity by the organs was calculated from the 3H activity in each organ divided by plasma-specific activity of [3H]TG and expressed per mg wet tissue weight. Values were corrected for plasma radioactivity present in the respective tissues.

**Liver lipids**

Lipids were extracted from livers of WT and CD36<sup>-/-</sup> mice fed a HFD for 11 weeks according to a modified protocol from Bligh and Dyer. Briefly, small liver pieces were homogenized in ice-cold methanol. After centrifugation, lipids were extracted by addition of 1800 µL
CD36 AFFECTS ADIPOCYTE LIPOLYSIS

chloroform: methanol (3:1 v/v) to 45 μL homogenate. The chloroform phase was dried and dissolved in 2% Triton X-100. Hepatic TG and total cholesterol (TC) concentrations were measured using commercial kits (11488872 and 236691, Roche Molecular Biochemicals, Indianapolis, IN, respectively).

Hepatic phospholipid (PL) concentrations were measured using the commercial available kit phospholipids B (Wako Chemicals GmbH, Neuss, Germany). Liver lipids were expressed per mg protein, which was determined using the BCA protein assay kit (Pierce).

**Determination of adipocyte size, adipocyte lipolysis and preadipocyte differentiation capacity**

To measure adipocyte size, mice were fed a HFD for 6 weeks and sacrificed. Gonadal, visceral and subcutaneous fat pads were removed and kept in PBS. It was decided to perform the adipocyte morphology and functionality experiments at the week 6 time point to be sure that metabolic adaptions to a HFD were still occurring in the animals and a new set-point had not yet been reached. The tissue was minced and digested in 0.5g/l collagenase in HEPES buffer (pH 7.4) with 20 g/l of dialyzed bovine serum albumin (BSA, fraction V, Sigma, ST Louis, USA) for 1 h at 37°C. The disaggregated adipose tissue was filtered through a nylon mesh with a pore size of 236 μm. For the isolation of mature adipocytes, cells were obtained from the surface of the filtrate and washed several times. Cell size was determined using an imaging processing technique implemented in MATLAB which automatically determines adipocyte sizes of hundreds of adipocytes from microscopic pictures of isolated adipocytes (~1000 cells/fat tissue sample). A manuscript describing the method is under preparation. From the measured cells the adipocyte size distribution, mean adipocyte diameter and adipocyte number per fat pad were determined. Also the volume-weighted mean adipocyte diameter was calculated, which is a measure of the mean adipocyte diameter corrected for the amount of fat that an adipocyte can store. In addition, the anti-lipolytic effect of insulin was determined in the adipocytes by incubating them for 2 h at 37°C in DMEM/F12 with 2% BSA in combination with or without 8-bromoadenosine 3’-5’-cyclic monophosphate (8b-cAMP) (10⁻³M) (Sigma) and/or insulin (10⁻¹¹M, 10⁻⁹M and 10⁻⁷M). Glycerol concentrations (index of lipolysis) were determined using a commercially available free glycerol kit (Sigma) with the inclusion of the hydrogen peroxide sensitive fluorescence dye Amplex Ultra Red, as described by Clark et al.

For the isolation of preadipocytes, the infranatant of the adipose tissue filtrate was centrifuged at 200 x g for 10 min at room temperature and treated with erythrocyte lysis buffer. The cells were washed 2 times, re-suspended in DMEM/NUT.MIX.F12 medium and supplemented with 10% fetal calf serum (FCS) and 100 μg/ml penicillin-streptomycin and inoculated into 96-well plates (6 wells/adipose tissue region) at a density of 30 000 cells/ml and kept at 37°C, in 5% CO₂. The cells were expanded until confluence after which adipocyte differentiation was induced using an adipogenic medium containing DMEM/F12 with dexamethasone 0.1µM, 3-isobutyl-1-methylxanthine (IBMX) 25µM, insulin 17 nM, indomethacin 60µM, 10% FCS and 100 μg/ml penicillin-streptomycin. After 4 days medium was changed to maintenance medium containing insulin 17 nM and 10% FCS. After 1 more
...day the cells were lipid filled and intra cellular lipid accumulation was determined using a fluorometer after incubating the cells with Nile Red (Sigma-Aldrich, St. Louis, MO).

Adipose tissue cyclic AMP level, RNA isolation and qPCR analysis

Adenosine 3’-5’-cyclic monophosphate (cyclic AMP, cAMP) levels were determined in gonadal fat samples of mice fed a HFD for 6 weeks using the cAMP direct immunoassay kit from Biovision (Biovision, Inc, Milpitas, CA) according to the instructions of the manufacturer. RNA from gonadal fat of mice was isolated using the Nucleospin RNA /Protein kit (Macherey-Nagel, Düren, Germany) according to the instructions of the manufacturer. The quality of each mRNA sample was examined by lab-on-a-chip technology using Experion Stdsens analysis kit (Biorad, Hercules, CA). 600 ng of total RNA was reverse-transcribed with iScript cDNA synthesis kit (Bio-Rad) and obtained cDNA was purified with Nucleospin Extract II kit (Macherey-Nagel). Real-Time PCR was carried out on the IQ5 PCR machine (Biorad) using the Sensimix SYBR Green RT-PCR mix (Quantace, London, UK) and QuantiTect SYBR Green RT-PCR mix (Qiagen). mRNA levels were normalized to mRNA levels of glyceraldehyde-3-phosphate dehydrogenase (Gapdh). Primer sequences are listed in table 1.

Hyperinsulinemic euglycemic clamp analysis

To assess insulin sensitivity mice were fed a HFD for 11 weeks. Hyperinsulinemic euglycemic clamps were performed as described earlier. Briefly, after an overnight fast, animals were anesthetized as described above and an infusion needle was placed in the tail vein. Basal glucose parameters were determined during a 60-min period, by infusion of D-[3-3H]glucose to achieve steady-state levels. A bolus of insulin (3 mU) was given and

F4/80, marker for macrophages; MRC-1, mannose receptor 1; MCP-1, monocyte chemotactic protein-1; IL-6, interleukin-6; IL-10, interleukin-10; HSL, hormone sensitive lipase; ATGL, adipose triglyceride lipase; CD45, marker for leukocytes; CD31, marker for endothelial cells; GAPDH, glyceraldehyde-3-phosphate dehydrogenase.
a hyperinsulinemic euglycemic clamp was started with a continuous infusion of insulin (5 mU/h) and D-[3-\(^{3}\)H]glucose and a variable infusion of 12.5% D-glucose (in PBS) to maintain blood glucose levels at euglycemic levels. Blood samples were taken every 5-10 min from the tip of the tail to monitor plasma glucose levels (AccuCheck). Seventy, eighty and ninety minutes (steady-state) after the start of the clamp, blood samples (70 μl) were taken for determination of plasma glucose and insulin using commercially available kits (Instruchemie and Crystal Chem Inc). Turnover rates of glucose (μmol/min/kg) were calculated during the basal period and in steady-state clamp conditions as the rate of tracer infusion (dpm/min) divided by the plasma-specific activity of \(^{3}\)H-glucose (dpm/μmol). All metabolic parameters were expressed per kilogram of body weight. The hepatic glucose production (EGP) is calculated from the rate of disappearance (Rd) and glucose infusion rate (GIR) by the following equation: Rd = EGP + GIR. The Rd is measured from Steele’s equation in steady state using the tracer infusion rate (Vin) and plasma-specific activity (SA) of \(^{3}\)H-glucose (dpm/μmol) by the following formula: Rd = Vin/SA.

### Statistical analysis

Data are presented as means ± SD. Statistical differences were calculated using the nonparametric Mann-Whitney test or two-way-ANOVA (SPSS 16, SPSS Inc, Chicago, IL). A P-value < 0.05 was regarded statistically significant.

### 2.3 RESULTS

#### CD36-deficiency reduces high fat diet-induced obesity

To induce obesity, male CD36\(^{-/-}\) and WT mice were fed a HFD containing 45 energy% fat for 12 weeks, and body weight of the mice was followed during the HFD intervention. CD36\(^{-/-}\) mice gained less body weight than WT mice (Fig. 1A). After 11 weeks, body composition was determined by DEXA analysis. As compared to WT mice, lean body mass was similar, but total body fat was 36% lower in CD36\(^{-/-}\) mice (5.8 ± 1.6 versus 9.0 ± 3.1 g; P<0.05) (Fig. 1B). In line with this observation, weights of isolated fat pads were lower in CD36\(^{-/-}\) mice (gonadal fat -38%; P<0.01, visceral fat -35%; P<0.01, subcutaneous fat -31%; P<0.05) (Fig. 1C). When mice were fed a HFD for 6 weeks, similar differences in phenotype between WT and CD36\(^{-/-}\) mice were observed. Fat pad weights of CD36\(^{-/-}\) mice were significantly lower after 6 weeks of HFD (gonadal fat -48%; P<0.001, visceral fat -33%; P<0.01, subcutaneous fat -41%; P<0.001), while liver weight was significantly higher (data not shown).

#### CD36-deficiency decreases uptake of TG-rich particle derived FA by white adipose tissue

To confirm that CD36-deficiency affects the tissue-specific uptake of FA that are derived from TG-rich particles, the plasma clearance and organ distribution of \[^{1}\text{H}]\text{TO-labeled TG-rich
VLDL-like emulsion particles was evaluated in HFD-fed CD36-/- mice versus WT mice. CD36-deficiency did not affect the plasma half-life of $[^3H]$TO ($t_{1/2} = 5.0\pm1.7$ versus $6.0\pm1.3$ min) (Fig. 2A). These results indicate that CD36-/- mice have equal capacity to clear TG-derived FA from plasma. However tissue-distribution of these FA was different for the two mouse strains. CD36-deficiency significantly decreased the uptake of $[^3H]$TO-derived activity in the heart (-38%; $P<0.001$), gonadal fat (-29%; $P<0.01$) and visceral fat (-30%; $P<0.01$), while the uptake of $[^3H]$TO-derived activity in the liver (+42%; $P<0.01$) and spleen (+49%; $P<0.01$) was significantly increased in the CD36-/- mice (Fig. 2B). These results imply that CD36-deficiency increases the flux of FA derived from TG-rich particles towards the liver, while decreasing the flux of FA
towards the heart and WAT. Indeed, CD36-deficiency increased hepatic lipid content (+88%; P<0.001) (Fig. 2C), without affecting hepatic TC and PL levels (data not shown).

**CD36-deficiency decreases adipocyte size in all fat pads and impairs adipocyte recruitment in gWAT**

To investigate the effect of reduced FA uptake in adipose tissue on adipocyte morphology; adipocyte size distribution, volume-weighted mean adipocyte diameter and total adipocyte number were determined in isolated adipocytes from gonadal, visceral and subcutaneous fat pads from CD36−/− and WT mice fed a HFD for 6 weeks. In gonadal fat pads of CD36−/− mice less hypertrophic adipocytes (110-170 μM) were observed (Fig. 3A). For visceral and subcutaneous fat, the distribution was also shifted to the left. (Fig. 3B-C). Volume-weighted mean cell diameter was decreased in gonadal (-12%; P<0.001), visceral (-14%; P<0.01)
and subcutaneous fat pads (-18%; P<0.001) of CD36-/- mice, indicating indeed smaller adipocytes (Fig. 3D). In gonadal fat, but not in visceral or subcutaneous fat a decreased number of total adipocytes was observed (-65%; P<0.001) (Fig. 3E).

The number of adipocytes in adipose tissue is dependent upon the recruitment of preadipocytes out of the precursor pool that differentiate into adipocytes. The total number of cells in the stromal vascular fraction (SVF) (which includes the preadipocyte pool) was higher per gram of gonadal fat in CD36-/- mice (5.0 x 10^5 ± 3.3 x 10^5 versus 2.3 x 10^5 ± 5.3 x 10^4 cells; P<0.01), indicating that the preadipocyte pool may be larger in gonadal fat of CD36-/- mice. In contrast, for visceral and subcutaneous fat no differences were observed in number of cells in the SVF (visceral: 1.0 x 10^6 ± 7.4 x 10^5 versus 8.0 x 10^5 ± 2.6 x 10^5 and subcutaneous: 4.0 x 10^5 ± 3.0 x 10^5 versus 2.4 x 10^5 ± 8.2 x 10^4, respectively) (Fig. 3F).

The SVF is a mixture of cell types where preadipocytes, leukocytes and endothelial cells constitute the major cell populations. mRNA expression of DLK1, a preadipocyte marker, tended to be higher in gonadal fat pads of CD36-/- mice (CD36-/- mice had a 44% higher DLK-1 expression; P=0.09), whereas expression of CD45, a leukocyte marker, was lower in CD36-/- mice (-39%; P<0.01), and CD31, an endothelial cell marker, was similar for CD36-/- and WT mice (Fig. 4A). These data indicate that the increased number of cells in the SVF may be accounted for by an increased number of preadipocytes, but not of leukocytes or endothelial cells. The number of very small adipocytes (diameter <50 µm) on the other hand, was much lower in the gonadal adipose tissue of CD36-/- mice (-65%; P<0.001) (Fig. 4B) which may indicate that less adipocytes are being recruited within gonadal fat pads of CD36-/- mice on a HFD, resulting in a higher pool of preadipocytes that remains in their SVF. This is illustrated in Fig. 3A by the bimodal cell size distribution in the gonadal fat of WT mice as opposed to the single peak in the cell size distribution in CD36-/- mice.

**CD36-deficiency does not affect preadipocyte intra cellular lipid accumulation**

To further study the underlying mechanisms which may explain the morphology of adipocytes in CD36-/- mice the intra cellular lipid accumulation in these cells was determined. This was assessed using isolated preadipocytes from CD36-/- and WT mice that were differentiated in an adipogenic medium. No differences were observed in intra cellular lipid accumulation between CD36-/- and WT mice for all fat pad regions (Fig. 5).

**CD36-deficiency stimulates lipolysis but improves insulin-mediated inhibition of lipolysis**

Morphology of adipocytes is not only determined by uptake of FA which leads to TG storage, but also by the level of FA release due to lipolysis. To investigate if CD36 plays a role in lipolysis, basal lipolysis was determined in isolated mature gonadal adipocytes of CD36-/- versus WT mice. Only gonadal adipocytes were studied because only from the gonadal fat pad the yield of adipocytes was enough to perform these experiments. CD36-/- mice had higher glycerol release both expressed per gram adipose tissue (data not shown) and expressed as lipolysis per adipocyte, which was found for both unstimulated
Figure 3. CD36-deficiency decreases adipocyte size. Wild-type (WT) (solid line) and CD36-deficient (CD36−/−) (dashed line) mice were fed a HFD for 6 weeks. Gonadal (gWAT), visceral (vWAT) and subcutaneous (sWAT) white adipose tissues were dissected. Adipocytes were isolated and adipocyte size distribution was determined (A-C). Values are means (n=9-10). Volume-weighted mean diameter (D) and total number of adipocytes were calculated (E). Stromal vascular fraction (SVF) was obtained and total number of cells in SVF of gWAT, vWAT and sWAT was determined (F). Values are means ± SD (n=9-10); **P<0.01, ***P<0.001.
Figure 4. CD36-deficiency impairs adipocyte recruitment in gonadal WAT. Wild-type (WT) and CD36-deficient (CD36−/−) mice were fed a HFD for 6 weeks. Gonadal white adipose tissue (gWAT) was dissected and mRNA levels of DLK-1, CD45 and CD31 in gWAT were determined (A). Values are means ± SD (n=10); **P<0.01. In addition, the % of very small adipocytes (<50μM) in gWAT was calculated (B). Values are means ± SD (n=9-10); ***P<0.001.

Figure 5. CD36-deficiency does not affect preadipocyte lipid accumulation. Wild-type (WT) and CD36-deficient (CD36−/−) mice were fed a HFD for 6 weeks. Gonadal (gWAT), visceral (vWAT) and subcutaneous (sWAT) white adipose tissues were dissected and preadipocytes were isolated and differentiated in adipogenic medium. Lipid accumulation was determined with Nile Red. Values are means ± SD (n=9-10) (6 wells/adipose tissue region per mouse).

and 8-bromo-cAMP (8b-cAMP) stimulated cells (2.1 fold, 2.8 fold respectively; P<0.05) (Fig. 6A). To test whether the increased lipolysis was due to higher levels of the lipolytic enzymes adipose triglyceride lipase (ATGL) and hormone sensitive lipase (HSL), mRNA expression of these enzymes was determined. However, both ATGL and HSL mRNA were lower in gonadal adipose tissue of CD36−/− versus WT mice (-27%; P<0.01 and -48%; P<0.001, respectively) (Fig. 6B). On the other hand, cAMP levels, which are reported to stimulate lipolysis, were increased in gonadal fat samples of CD36−/− mice (+31%; P<0.05) (Fig. 6C). Also the suppression of lipolysis by insulin was investigated in CD36−/− versus WT mice. Inhibition of lipolysis by 3 different insulin concentrations (10−11, 10−9, 10−7 M) expressed as % of 8b-cAMP induced lipolysis was tested. An insulin concentration of 10−11M
already maximally suppressed lipolysis, since no further inhibition was found with insulin concentrations of $10^{-8}$ and $10^{-7}$ M (2 way ANOVA F=0.37; P=0.7). However inhibition of lipolysis was more potent in CD36−/− mice compared to WT mice (50% versus 29%; 2 way ANOVA F=10.65; P<0.01) (Fig. 6D). To investigate whether the increased adipocyte insulin sensitivity in lipolysis may be related to changes in adipose tissue inflammation, expression of inflammatory markers in gonadal adipose tissue was determined. As mentioned above, expression of CD45 was lower in CD36−/− mice. Moreover, a decreased expression of macrophage marker F4/80 (-29%; P<0.05) and a trend for higher IL-10 expression in gonadal adipose tissue of CD36−/− mice (+53%; P=0.08) (Fig. 6E) was observed.

**CD36-deficiency decreases hepatic insulin sensitivity**

To investigate the effect of decreased adiposity and increased hepatic lipid content on metabolic abnormalities such as insulin resistance, we performed a hyperinsulinemic euglycemic clamp after an o/n fast. Glucose (5.4 ± 0.7 versus 5.4 ± 0.7 and 5.8 ± 0.6 versus 5.6 ± 0.6 mM) and insulin levels (0.5 ± 0.2 versus 0.4 ± 0.2 and 4.0 ± 0.9 versus 4.5 ± 1.0 ng/mL) were equal for the 2 genotypes under basal as well as under hyperinsulinemic conditions. To maintain euglycemia during the insulin infusion, a similar amount of glucose was needed to be infused in CD36−/− mice compared to WT mice (GIR 25.7 ± 12.9 versus 28.1 ± 5.9 μmol/min/kg) (Fig. 7A). The glucose disposal rates under basal conditions were higher for CD36−/− animals (32.3 ± 8.8 versus 25.1 ± 4.3 μmol/min/kg; P<0.05). During hyperinsulinemic conditions glucose disposal rates were similar for CD36−/− and WT animals (55.2 ± 19.9 versus 43.7 ± 4.6 μmol/min/kg), indicating that there was no difference in peripheral insulin sensitivity between CD36−/− mice compared to WT mice (Fig. 7B). Nevertheless, the CD36−/− mice developed aggravated hepatic insulin resistance compared to WT mice as indicated by the higher hepatic glucose production during the hyperinsulinemia (29.3 ± 11.3 versus 15.5 ± 3.6 μmol/min/kg; P<0.01) (Fig. 7C).

**2.4 DISCUSSION**

The current study investigated the effects of CD36-deficiency on adipocyte morphology and functionality during HFD to get a better understanding of the role of CD36 in adipocytes.

In accordance with others, we found less adiposity in CD36−/− mice, which was due to a reduced uptake of FA in the adipose tissues. A decrease in fat pad mass can be caused by smaller adipocytes and/or by a decreased number of adipocytes. The CD36−/− mice showed less hypertrophy of their gonadal, visceral and subcutaneous adipocytes and the volume-weighted mean cell diameters of all fat pads studied were significantly lower in the CD36−/− mice. Thus the smaller fat pads in the CD36−/− are due to smaller fat cells in their adipose tissues. Moreover, for the gonadal adipose tissue, the CD36−/− mice showed a lower total number of adipocytes. The gonadal (but neither visceral nor subcutaneous) adipose tissue of CD36−/− mice had
Figure 6. CD36-deficiency stimulates lipolysis but improves insulin-mediated inhibition of lipolysis. Wild-type (WT) and CD36-deficient (CD36-/-) mice were fed a HFD for 6 weeks. Gonadal (gW AT) was dissected and adipocytes were isolated. Adipocytes were incubated for 2 h at 37°C in DMEM/F12 with 2% BSA in combination with or without 8-bromo-cAMP (8b-cAMP) (10-3M). Glycerol concentrations (index of lipolysis) were determined using a fluorometric method (A). Values are means ± SD (n=5); *P<0.05. RNA was isolated from gWAT and mRNA levels of adipose triglyceride lipase (ATGL) and hormone sensitive lipase (HSL) were determined (B). Values are means ± SD (n=10); **P<0.01, ***P<0.001. gWAT cAMP levels were determined using an immunoassay kit (C). Values are means ± SD (n=9-10); *P<0.05. The anti-lipolytic effect of insulin was determined as % of 8b-cAMP induced lipolysis. Adipocytes were incubated with insulin (10^-11 M, 10^-9 M and 10^-7 M) Statistical analysis was done using 2 way ANOVA (D). Values are means ± SD (n=5). mRNA levels of macrophage marker F4/80, mannose receptor C1 (MRC-1), monocyte chemotactic protein-1 (MCP-1), interleukin 6 (IL-6) and interleukin 10 (IL-10) were determined (E). Values are ± SD (n=10); *P<0.05.
a larger pool of preadipocytes, and a reduced number of very small adipocytes (<50µm). These results suggest that less preadipocytes are being recruited to become adipocytes in the gonadal adipose tissue, resulting in a higher pool of preadipocytes that remains in the SVF. So the CD36−/− mice seem to have a reduced adiposity not only due to a reduced hypertrophy but also due to a reduced hyperplasia of the adipocytes, at least in the gonadal adipose tissue. The fact that the observed differences in preadipocyte recruitment seemed restricted to the gonadal tissue may be explained by the gonadal adipose tissue being the largest fat pad in the animals and that it has the largest fat cells, as also shown in this paper. We hypothesize that the gonadal adipose tissue was thus exposed to the highest metabolic stress and therefore the need for preadipocyte recruitment was probably the highest in this adipose tissue region. There were no differences in gene expression of CD36 between the subcutaneous and gonadal fat pads of WT mice (data not shown), so differential expression of CD36 cannot explain the observation that the gonadal fat is more affected. Gonadal fat depots are larger in male mice, both in absolute and relative terms. In male mice gonadal fat

Figure 7. CD36-deficiency decreases hepatic insulin sensitivity. Wild-type (WT) and CD36-deficient (CD36−/− mice) were fed a HFD for 11 weeks. After O/N fast a hyperinsulinemic euglycemic clamp was performed. Glucose infusion rate (GIR) (A), rate of disappearance during basal and hyperinsulinemic period (B) and hepatic glucose production during hyperinsulinemic period (C) were determined. Values are means ± SD (n=7-10 per group); *P<0.05, **P<0.01.
depots are larger than subcutaneous fat depots after HFD feeding, whereas in female mice the two fat depots are of almost equal size \(^\text{17}\). The current study investigated only male mice, because male mice are more susceptible to diet-induced obesity and diet-induced insulin resistance than female mice \(^\text{18}\). It remains to be studied whether in female mice changes in adipose tissue due to CD36-deficiency are less restricted to gonadal adipose tissue.

Interestingly, despite the in vivo differences in adipocyte size distributions, isolated preadipocytes showed equal intra cellular lipid accumulation in vitro for CD36\(^{-/-}\) mice and WT for all fat depots. Our results are in line with a recent study from Cai et al. that also showed similar differentiation capacity of the SVF of adipose tissue between WT and CD36\(^{-/-}\) mice \(^\text{19}\). These in vitro observations may be explained by de novo lipogenesis from carbohydrates present in the culture medium. Collins et al. have shown that de novo lipogenesis in differentiating adipocytes can provide all the FA that are necessary for adipocyte maturation. They showed this using an in vitro model of human preadipocytes which are cultured under serum free conditions without any exogenous fat \(^\text{20}\). We added 10% FCS to our mouse preadipocyte cultures - as these cells cannot survive under serum free conditions- and serum contains FA. Despite the availability of exogenous FA as an energy source in our in vitro experiments, uptake of FA may have been by-passed and glucose was used instead to synthesize FA intracellularly. The fact that the gonadal adipose tissue of CD36\(^{-/-}\) mice showed a reduced preadipocyte recruitment in the in vivo experiments may have been due to the high fat diet, which puts a maximum pressure on the expandability of the adipose tissue. The WT mice were able to cope with the FA overload by delivering them to the existing mature adipocytes as well as to the preadipocytes, whereas in the CD36-deficient mice neither mature adipocytes nor preadipocytes could efficiently take up the excess of FA. During preparation of this manuscript, a study was published by Christiaens et al. that showed impaired adipogenesis of 3T3-F442A preadipocytes upon CD36 silencing during preadipocyte differentiation \(^\text{21}\). Whether the discrepancies between the studies are due to differences in cell type and/or CD36 expression level (none in our CD36\(^{-/-}\) cells, low in the knock-down 3T3-F442A cell line) remains to be determined.

Gonadal adipocytes of CD36\(^{-/-}\) mice showed increased basal and 8b-cAMP induced lipolysis. Published literature suggests that large adipocytes have a higher rate of lipolysis \(^\text{22}\). However, we observed a higher basal- and 8b-cAMP stimulated lipolysis in adipocytes from CD36\(^{-/-}\) mice, despite the decreased volume of these adipocytes. The increased lipolysis might be explained by diminished product inhibition of HSL by FA. Since CD36-deficiency impairs FA uptake by adipocytes, less FA might be present intracellularly which may lead to decreased product inhibition of HSL. Recently, it has been shown that long chain FA reduce production of cAMP which results in a decreased phosphorylation of HSL. \(^\text{23}\). Moreover, it has been shown that A-FABP null mice have decreased lipolysis, while E-FABP transgenic mice have increased lipolysis \(^\text{24}\). This was explained by FABP being able to bind FA, thereby relieving product inhibition of HSL. We found an unexpected decrease in mRNA levels of ATGL and HSL in adipose tissue of CD36\(^{-/-}\) mice compared to expression in WT mice. However cAMP levels were increased in CD36\(^{-/-}\) mice, which results in increased phosphorylation of HSL rather than increased expression and thus may explain
the increased lipolysis. Since muscle normally relies on FA, it might also be that in CD36−/− mice there is a continuous signal from muscle to fat to release more FA and/or that there is absence of a stop signal to inhibit adipocyte lipolysis. Our results are in contrast with Zhou et al. who reported similar basal lipolysis and phosphorylation of HSL by WT and CD36−/− adipose tissue. This discrepancy could be due to the fact that Zhou et al. measured rates in incubated tissue versus adipocytes in the present study.

Insulin was more potent in inhibiting lipolysis in the CD36-deficient mice, suggesting higher insulin sensitivity of the adipocytes. Hypertrophic subcutaneous adipocytes were associated with increased insulin resistance. The fact that CD36−/− mice have less hypertrophic adipocytes could therefore help to explain the more potent inhibition of lipolysis by insulin. Kennedy et al. also observed increased insulin sensitivity in adipocytes from CD36−/− mice. They discovered that adipose tissue of HFD-fed CD36−/− mice is less inflamed, which could explain the increased insulin sensitivity. In accordance with these findings, we measured a decreased expression of the leukocyte marker CD45 as well as the macrophage marker F4/80 and found a trend towards higher expression of the anti-inflammatory cytokine IL-10 in gonadal adipose tissue of the CD36 deficient mice.

The observed reduction in body weight of CD36−/− mice on HFD is in accordance with recent studies by others, although the effect was less pronounced in our study (-6% versus -23% and -51% respectively). The smaller effect on body weight gain could be due to differences in HFD composition. We used a HFD containing 45 energy% of fat, whereas others used a HFD containing 60 energy% of fat.

The reduced FA uptake in adipose tissue in CD36 deficient mice was paralleled by a reduced uptake in heart and an increased FA uptake in the liver and spleen. In contrast to the heart and muscle, CD36 is not a major facilitator of FA uptake in the liver, therefore FA uptake was not affected by the loss of CD36. Instead, the impaired uptake of FA in other peripheral organs such as muscle and adipose tissue results in a higher flux of FA to the liver. Our findings are partly in accordance with the study of Coburn et al. which showed that uptake of FA analogs was decreased in muscle and adipose tissue of chow-fed CD36−/− mice. We also found that the decreased FA uptake is solely caused by a lack of the FA transporter CD36 and not due to reduced capacity of lipoprotein lipase (LPL), since we found an even higher post-heparin LPL activity in CD36−/− mice (data not shown), probably due to compensatory mechanisms.

The livers of the CD36-deficient mice contained more TG and were more insulin resistant as indicated by the higher hepatic glucose production under hyperinsulinemic conditions. It is well established that ectopic fat deposition in the liver contributes to development of hepatic insulin resistance. Although the adipocytes of the CD36−/− mice showed increased insulin sensitivity in vitro; in vivo, we did not observe increased peripheral insulin sensitivity. This could be due to the fact that glucose uptake in adipose tissue under hyperinsulinemic conditions is relatively small. Under these conditions, most of the glucose is taken up by heart and muscle.

One hypothesis to explain FA trafficking towards other places than adipose tissue, is the so called 'sick adipose tissue' hypothesis. According to this hypothesis unhealthy adipose tissue
consists of hypertrophic cells due to impaired creation of new adipocytes. Ultimately, these hypertrophic adipocytes become dysfunctional which results in increased FA release leading to increased FA availability to nonadipose tissues. Our study shows that CD36-deficiency also leads to ‘sick adipose tissue’. However, in this case the adipose tissue has dysfunctional adipocytes which cannot store an overload of FA together with an impaired ability to recruit new adipocytes. As a consequence, the FA are translocated to the liver. Despite the lack of hypertrophic adipocytes, CD36 deficient adipose tissue has an unexpected higher FA release during basal lipolysis which even further increases the availability of FA to the liver. Therefore it appears that CD36 plays an important role in adipose tissue functionality- both by regulating FA uptake and release- and likewise the distribution of fat to adipose and non-adipose tissues.
