Chapter 3

Prognostic value of interpretation consistency of MR Imaging in sciatica

Submitted for publication
**ABSTRACT**

**PURPOSE**

To evaluate the clinical outcome results of patients with sciatica according to consistency in Magnetic resonance imaging (MRI) interpretation among spine specialists.

**METHODS**

Patients for this study were participants who underwent a baseline MRI to assess the eligibility for a randomized trial designed to compare the efficacy of early surgery with prolonged conservative care for patients with sciatica. Two neuroradiologists and one neurosurgeon independently evaluated all MRIs. (In)consistent MRI interpretation was correlated with patient’s report of perceived recovery, Roland Disability Questionnaire (RDQ) and visual-analogue scale (VAS) for leg and back pain at one year.

**RESULTS**

Of the 389 patients the three MRI observers agreed in 296 (76%) patients about the presence of a disc herniation, disagreed in 48 (12%) patients about its presence and agreed in 45 (12%) patients about its absence. Of the patients with a (consistent) disc herniation on MRI 84% reported perceived recovery after one year compared to 75% of the patients with inconsistent interpretation and 58% of the patients in whom all three readers agreed about the absence of a herniated disc (P<0.001). The same pattern was observed with the RDQ score (P=0.007), VAS leg pain (P=0.06) and VAS back pain (P=0.001). Patients with a (consistent) disc herniation had the highest speed of perceived recovery, followed by patients with inconsistent interpretation and those with absence of disc herniation (P=0.006).

**CONCLUSION**

At one year follow-up the most favorable clinical outcome results were reported by those patients in whom all three MRI observers independently agreed about the presence of disc herniation, followed by those with inconsistent interpretation and by those with absence of those findings at baseline.
INTRODUCTION

Sciatica is one of the most common lumbar-spine disorders. It is characterized by radiating pain in an area of the leg typically served by one nerve root in the lumbar or sacral spine and is occasionally accompanied by neurological deficit. The most common cause of sciatica is a herniated disc. The prevalence of sciatic symptoms varies considerably ranging from 1.6% in the general population to 43% in a selected working population. Sciatica results in severe pain and disability for the individual patient and significant costs in terms of treatment, sick leave, and pensions for society.

Magnetic resonance imaging (MRI) is considered the imaging procedure of choice for patients suspected of lumbar herniated discs and is indicated in patients with severe symptoms who fail to respond to conservative care for at least 6 to 8 weeks. If a herniated disc with nerve root compression is indeed present surgery as a treatment modality might be considered. About 20 to 30% of the patients with sciatica finally receives surgery. Depending upon the used outcome measure, the results of lumbar disc surgery are unsatisfactory in 15 to 40% of the patients. It has been suggested that the poor outcomes following lumbar disc surgery may be more often due to the errors in diagnosis than failure of the surgical intervention or its complications. For example, a false-positive diagnosis of a herniated disc with nerve root compression on MRI may lead to unwarranted surgery and subsequently a poor clinical outcome. Therefore, we hypothesized that patients in whom spine specialists independently agree about the presence of a disc herniation might fare better than those with inconsistent interpretation or those in whom spine specialists independently agree about the absence of a disc herniation.

The researchers previously reported the results of a randomized controlled trial comparing early surgery with prolonged conservative care for patients with sciatica. The trial showed faster recovery after early surgery compared to a strategy of prolonged conservative care with surgery if needed, but without any differences in the clinical outcomes after one year. The randomized patients were part of a larger group of patients with sciatica who underwent MRI and were followed up for one year. We now report on the clinical outcome of patients with sciatica in whom spine specialists independently agreed about the presence of a disc herniation or nerve root compression, those with inconsistent MRI interpretation, and those in whom spine specialists independently agreed about the absence of those findings.

METHODS

STUDY POPULATION

Patients for this study were participants who underwent an MRI to assess the eligibility for a multicenter, prospective, randomized controlled trial designed to determine whether early
surgery results in a more effective outcome compared to a strategy of prolonged conservative treatment with surgery if needed among patients with 6 to 12 weeks sciatica. Patients who had symptoms being so severe that they were eligible for surgery according to their general practitioners were referred to the neurologist who subsequently evaluated whether these patients were eligible to participate in the trial. Patients were excluded if they were presenting with cauda equina syndrome, insufficient strength to move against gravity, identical complaints in the previous 12 months, previous spine surgery, pregnancy or severe coexisting disease. Patients who were not between 18 to 65 years of age were also excluded. All participants who were not meeting one or more of the aforementioned exclusion criteria and had a lumbosacral radicular syndrome lasting between 6 to 12 weeks underwent MRI. MRIs of all patients, regardless of participation in the randomized clinical trial, were again evaluated by independent observers. The medical ethics committees at the nine participating hospitals approved the protocol. Written informed consent was obtained from all patients. Details of the design and study protocol of the randomized controlled trial have been published previously. In the present study, however, the data were analyzed as a cohort study.

MRI protocol and evaluation

MRI scans were performed in all 9 participating hospitals with the use of standardized protocols tailored to a 1.5 Tesla scanner. Sagittal T1-weighted images and axial T1-weighted spin–echo images of the lumbar spine were obtained, as well as T2-weighted sagittal and axial series and contrastenhanced (gadolinium) fat-suppressed T1-weighted images.

Two neuroradiologists (BK and GL) and one neurosurgeon (CV) independently evaluated all MR images, blinded to clinical information. None of the readers had been involved in either the selection or care of the included patients. Observer experience in reading spine MRI’s was 7 and 6 years post-residency for the neuroradiologists and 4 years post-residency for the neurosurgeon. The observers hold senior positions in busy spinal clinics with a focus on advanced spine surgery, and are confronted with spinal MRIs on a daily basis.

For both the presence of disc herniation and nerve root compression a four point scale was used: 1 for definite presence, 2 for probable presence if there was some doubt but the probability was greater than 50%, 3 for possible presence if there was reason to consider but the probability was less than 50%, and 4 for definite absence. For each MRI observer the evaluations on the 4 point scale were dichotomized: the first two categories were combined and marked as herniated disc or nerve root compression present, the last two categories were combined and marked as absence of the abnormalities. Readings between the MRI observers were considered inconsistent when one of the three MRI observers had a different evaluation based on the dichotomized (made) scale.
OUTCOMES

The patients were assessed by means of the Roland Disability Questionnaire for Sciatica (RDQ, scores range from 0 to 23, with higher scores indicating worse functional status),\textsuperscript{15} the 100-mm visual-analogue scale (VAS) for leg and back pain (with 0 representing no pain and 100 the worst pain ever experienced),\textsuperscript{16} and a 7-point Likert self-rating scale of global perceived recovery given by the question whether the patient experienced recovery, with answers ranging from completely recovered to much worse. Perceived recovery was defined as “complete” or “nearly complete disappearance of symptoms” on the patient-reported 7-point Likert scale for global perceived recovery, while a score in the remaining five categories was marked as “no recovery”.\textsuperscript{13} Outcome measures were assessed at baseline, 2, 4, 8, 12, 26, 38 and 52 weeks. Patients were blinded to results of earlier assessments.

STATISTICAL ANALYSIS

The total study population was divided into three groups: a group with consistent MRI interpretation regarding the presence (i.e. all three readers independently agreed about the presence of a disc herniation or nerve root compression), a group with inconsistent MRI interpretation (i.e. one reader disagreed with the other two), and a group with consistent MRI interpretation regarding the absence. Differences between the three groups in clinical outcome at one year were assessed by using one-way analysis of variance (ANOVA) for continuous data and Chi-square test for categorical data. Time from baseline until perceived recovery (as determined by the prescheduled moments of outcome registration during the first year) was compared between the three groups by use of Kaplan-Meier curves and analyzed by Cox proportional-hazards models.

We assumed clinical outcome data to be missing at random and used model-based multiple imputation to impute the outcome values, a method in which the distribution of the observed data is used to construct sets of plausible values for the missing observations (10 imputed datasets). Variables included in the model were age, gender, body-mass index, duration of symptoms, smoking, treatment group (randomized to surgery, randomized to prolonged conservative care or non-randomized), MRI variables (presence of disc herniation, presence of nerve root compression and corresponding disc level), and baseline and other follow-up measurements of the outcomes being predicted. Complete case analysis (i.e. no imputation) was performed as a sensitivity analysis. Statistical significance was defined as $P < 0.05$.

RESULTS

Of the 599 patients screened for the study, 395 patients considered eligible for inclusion underwent MRI of whom 283 patients were randomized.\textsuperscript{13} In total, 106 baseline MRIs of the 112 non-randomized patients and 283 MRIs of the 283 randomized patients could be retrieved,
bringing the total to 389 MRIs. The study population had a mean age of 43.2 years with the majority being men (63%). The mean duration of sciatica was 9.3 weeks. At baseline, the study population reported a mean RDQ of 16.0, VAS-leg pain of 63.2 mm and VAS-back pain of 33.5 mm. Clinical outcome at 52 weeks was missing in 13-14% of patients (Appendix Table

Figure 1 Axial and sagittal T2 images of 1 patient in whom all 3 MRI observers agreed about the presence of disc herniation at disc level L5-S1 (A and B, arrows), and of 1 patient in whom the 3 MRI observers disagreed whether a disc herniation is visible at disc level L5-S1 (C and D, arrows)
RDQ, VAS-leg and VAS-back pain were comparable among patients for whom clinical outcome at 52 weeks was available and those for whom not (P-value range 0.20-0.39).

Of the 389 patients, the three observers independently agreed in 296 (76%) patients about the presence of a disc herniation, disagreed in 48 (12%) patients about its presence and agreed in 45 (12%) patients about its absence (Table 1). An example of complete agreement among the three observers about the presence of a disc herniation and an example of disagreement is shown in Figure 1.

Of the patients with a (consistent interpretation of) disc herniation on MRI 84% reported perceived recovery after one year compared to 75% of the patients with inconsistent interpretation and 58% of the patients in whom all three readers agreed about the absence of a herniated disc (P<0.001). The same pattern was observed with the RDQ score (P=0.007), VAS leg pain (P=0.06) and VAS back pain (P=0.001) (Table 2). When comparing the three groups pairwise no statistical significant difference was observed between patients with a disc herniation and those with inconsistent interpretation in any of the four outcome measures, but statistical significant differences were observed between the group with absence of a disc herniation compared with the group with a disc herniation or the group with inconsistent interpretation.

Of the 389 patients, the three observers agreed in 262 (67%) patients about the presence of nerve root compression, disagreed in 70 (18%) patients about its presence and agreed in 57 (15%) patients about its absence (Table 1). Of the patients with (consistent interpretation of) nerve root compression 86% reported perceived recovery after one year compared to 83% of the patients with inconsistent MRI interpretation and 49% of the patients in whom all three readers agreed about the absence of nerve root compression (P<0.001) (Table 2). The same pattern was observed with the RDQ score (P<0.001), VAS leg pain (P=0.001) and VAS back pain (P<0.001). Again, when comparing the three groups pairwise no statistical significant difference was observed between the patients with nerve root compression and those with inconsistent interpretation in any of the four outcome measures, but statistical significant differences were observed between the group with absence of nerve root compression compared with the group with nerve root compression or the group with inconsistent interpretation.

Results stratified by treatment group are shown in Table 3. Only 4 patients had absence of disc herniation in the group randomized to surgery or prolonged conservative care In all three treatment groups the same pattern was observed regarding nerve root compression: patients with absence of nerve root compression had the worse clinical results compared to those with nerve root compression or inconsistent interpretation (Table 3B).

The Kaplan-meier curves show that patients with a (consistent interpretation of) disc herniation had the highest speed of perceived recovery, followed by patients with inconsistent interpretation and those with absence of disc herniation (P=0.006) (Figure 2A). Patients with absence of nerve root compression also had a lower speed compared to those with nerve root compression or inconsistent interpretation (P=0.006) (Figure 2B and Table 4).

Sensitivity analyses performed to account for missing clinical data yielded similar results (Table S2 and Table S3 Supplementary Appendix).

Chapter 3

Discussion

The present study analyzed the significance of MRI interobserver variability among three spine specialists for the one-year outcomes in patients with sciatica who were potential candidates for lumbar disc surgery based on clinical grounds. The most favorable clinical outcome results after one year follow-up were reported by those patients in whom all three MRI observers independently agreed about the presence of disc herniation or nerve root compression, followed...
by those with inconsistent interpretation and finally by those in whom independent agreement was reached about the absence of those abnormalities.

The direct evaluation of herniated discs and nerve roots by MRI has been considered an important asset to facilitate decision making in patients with leg and/or back pain.\textsuperscript{5,17,18} Uncertainty on the presence of a herniated disc with nerve root compression will in most cases result in conservative treatment, while a certain herniated disc with nerve root compression will in most cases result in surgery.\textsuperscript{11} However, as with any diagnostic radiographic study, interpretation of the results regarding the presence of a herniated disc and nerve root compression may become inconsistent between examiners.\textsuperscript{11,19-22} It has been suggested that inconsistency in interpretation may lead to alternative treatment options between clinicians and therefore may impact the outcome of patient treatment.\textsuperscript{19} Variations in rates of spinal surgery may be related in part to substantial variability among physicians in interpreting the abnormalities identified with lumbar MRI.\textsuperscript{23} The results of the present study suggest that based on the consistency in interpretation by the MRI assessors prognostic profiles can be made in sciatica, and that the mechanism behind these prognostic profiles is probably related to whether there is truly a disc herniation or nerve root compression present (if present a favorable prognosis compared with unfavorable when absent). The presence of nerve root compression in patients with sciatica has earlier been reported to be associated with favorable prognosis in primary care patients with sciatica.\textsuperscript{24}

Principles of rational medicine suggest that outcomes can be improved by providing physicians better diagnostic data that clarify disease characteristics.\textsuperscript{25,26} Clinical outcomes might be poorer when patient heterogeneity is not recognized, leading to a mismatch between patient subgroups and intervention type.\textsuperscript{26,27} The current study show that indeed the best clinical treatment results after one year follow-up are reported by those patients in whom MRI observers agreed regarding the presence of a disc herniation or nerve root compression as compared to those with inconsistent interpretation or those with absence of those findings. Tremendous effort has been put in uncovering the relationship between specific imaging characteristics and patient outcomes in sciatica, which unfortunately remains controversial.\textsuperscript{28,29} To gain more insight in the relationship between specific imaging characteristics and patient outcomes, those interpreting the images must reliably assess the finding. One reason that a prediction model might lose its predictive power is the incorrect assessment of MRI findings (the predictors), which causes the inputs in the prediction model to be faulty.\textsuperscript{30} Therefore, it is not only from a clinical but also from a research perspective crucial that radiologists and clinicians strive to reduce variability in interpretation.\textsuperscript{31} In the current study the MRI observers disagreed in nearly one fifth regarding the presence of nerve root compression. Specific training and defining the language for image interpretation for degenerative disc disease have been proposed to reduce variability in interpretation.\textsuperscript{30,31}

We deliberately did not organize a consensus meeting in which a sample of images was evaluated. Such a meeting could have caused the observers to adjust their diagnostic imaging
criteria and could have overestimated consistency compared to the situation as it existed before the study. However, our study has several shortcomings. The concordance found in this study may have been overestimated, since one reading pair consisted of two neuroradiologists who had nearly the same observer experience and also worked together which may have led to an informal agreement in their diagnostic criteria. The concordance might also have been overestimated since a great part of our study sample consisted of a relatively homogeneous study sample with well-defined inclusion criteria and known sciatica due to previous confirmed disc herniation by another observer. The found concordance is likely to be higher compared to a study sample consisting of patients in whom diagnosis was not confirmed as well as those who are confirmed to have or not to have disc herniation. And finally, the study population of the present study consisted of sciatica patients who had severe symptoms for at least 6 weeks and were referred to the neurologists. These patients were willing to undergo surgery, so patients with a clear preference for conservative treatment are underrepresented.

In conclusion, at one year follow-up the most favorable clinical outcome results were reported by those patients in whom all three MRI observers independently agreed about the presence of disc herniation or nerve root compression, followed by those with inconsistent interpretation and finally by those with absence of those findings.

INFORMED CONSENT
All procedures followed were in accordance with the ethical standards of the responsible committee on human experimentation (institutional and national) and with the Helsinki Declaration of 1975, as revised in 2000. Informed consent was obtained from all patients for being included in the study.

ACKNOWLEDGEMENT
This study was funded by grants from the Health Care Efficiency Research Program of Netherlands Organisation for Health Research and Development (ZonMw) and the Hoelen Foundation, The Hague. There were no agreements concerning confidentiality of the data between the funders and the authors or the participating institutions. The funders did also not have any role in the writing or analysis of this study, nor in the decision to publish the paper.
