ABSTRACT

We present a method for studying the secular gravitational dynamics of hierarchical multiple systems consisting of nested binaries, which is valid for an arbitrary number of bodies and arbitrary hierarchical structure. We derive the Hamiltonian of the system and expand it in terms of the assumed small ratios $x_i$ of binary separations. At the lowest non-trivial expansion order (quadrupole order, second order in $x_i$), the Hamiltonian consists of terms which, individually, depend on binary pairs. At higher orders, in addition to terms depending on binary pairs, we also find terms which, individually, depend on more than two binaries. In general, at order $n$ in $x_i$, individual terms depend on at most $n - 1$ binaries. We explicitly derive the Hamiltonian including all terms up and including third order in $x_i$ (octupole order), and including the binary pairwise terms up and including fifth order in $x_i$. These terms are orbit averaged, and we present a new algorithm for efficiently solving the equations of motion. This algorithm is highly suitable for studying the secular evolution of hierarchical systems with complex hierarchies, making long-term integrations of such systems feasible. We show that accurate results are obtained for multiplanet systems with semimajor axis ratios as large as $\approx 0.4$, provided that high-order terms are included. In addition to multiplanet systems with a single star, we apply our results to multistar systems with multiple planets.

Key words: gravitation – celestial mechanics – planet–star interactions – stars: kinematics and dynamics.

1 INTRODUCTION

Stellar multiple systems are often arranged in a hierarchical configuration composed of binary orbits (Evans 1968; Nukeyre & Bouvier 1981). For most systems, these orbits are nearly Keplerian on short time-scales. The simplest and most common configuration is a hierarchical triple, in which the centre of mass of a binary is orbited by a tertiary companion. Observed triples are, by necessity, dynamically stable on time-scales of the order of the orbital periods. However, on time-scales much longer than the orbital periods, exchanges of torques can give rise to secular oscillations in the eccentricities of the orbits, i.e. Lidov–Kozai (LK) oscillations (Kozai 1962; Lidov 1962). These oscillations have important implications for e.g. short-period binaries (Mazeh & Shaham 1979; Kiseleva, Eggleton & Mikkola 1998; Eggleton & Kiseleva-Eggleton 2001; Eggleton & Kiseleva-Eggleton 2006; Fabrycky & Tremaine 2007; Naoz & Fabrycky 2014).

Similar oscillations can occur in quadruple systems, which are observed in two hierarchical configurations. In the ‘2+2’ or ‘binary–binary’ configuration, two binaries orbit each other’s barycentre (e.g. Pejcha et al. 2013, who studied the secular dynamics using $N$-body integration methods). In the ‘3+1’ or ‘triple–single’ configuration, a single body orbits the centre of mass of a hierarchical triple (Hamers et al. 2015). Quintuple and even higher order systems are also observed, although with lower frequency (e.g. Tokovinin 2014a,b). The number of possible configurations of hierarchical $N$-body systems composed of nested binaries increases with $N$, and is $N - 2$ for $N \ge 3$ (Nukeyre & Bouvier 1981). This suggests a large variety of high-$N$ systems (e.g. van den Berk, Portegies Zwart & McMillan 2007).

Even more complex hierarchies arise when considering exoplanets. Since the past decade, planets are being discovered at an exponential rate, and an increasing number of exoplanets are observed in binary, triple and even quadruple systems. In the simplest case of stellar binaries, planets have been observed orbiting an individual star (S-type orbits, in the nomenclature of Dvorak 1982) and orbiting a stellar binary (P-type orbits). Approximately 70 S-type planets in binaries have been found so far (Roell et al. 2012). Fewer
circumbinary (or P-type) planets have been found; e.g. nine Kepler transiting circumbinary planets have been found so far (e.g. Winn & Fabrycky 2015). However, detecting such planets is generally more difficult compared to S-type planets (Martin & Triaud 2014); it has been estimated that the occurrence rate of P-type planets could be as high as the occurrence rate of exoplanets around single stars (Armstrong et al. 2014).

Although their detection is still severely limited by observational biases, exoplanets have also been found in multistellar systems with more complex hierarchies. Examples include Gliese 667, a triple system with at least two planets orbiting the tertiary star (Bonfils et al. 2013; Feroz & Hobson 2014 and references therein), and 30 Arietis, a quadruple system with an S-type planet around one of the stars (Tokovinin et al. 2006; Guenther et al. 2009; Riddle et al. 2015; Roberts et al. 2015).

These observations indicate that planet formation in stellar multiple systems is not only possible, but may also be a common phenomenon. Multiplanet systems in multistellar systems give rise to complex hierarchies with many layers of binaries, starting from the largest binary, typically a wide stellar binary with periods as long as thousands of years, and ending with tight planetary orbits with periods as short as a few days. Moons enrich the complexity of this picture even more.

So far, the secular, i.e. long-term, dynamics of high-order multiple systems have hardly been explored. This is largely due to the computational complexity of integrating, with sufficient precision, dynamical systems with orbital periods differing by many orders of magnitude (Boekholt & Portegies Zwart 2015). An approximate, but nevertheless useful, approach is to average the Hamiltonian over individual orbits, effectively smearing out the point mass moving in each orbit into a ring. The resulting dynamics are that of interacting rings rather than point masses. The typical required time-step of the orbit-averaged equations of motion is a (sufficiently) small fraction of the secular time-scales, which are much longer than the orbital periods. This allows for much faster integration.

This method of averaging has a long history, dating back to the seminal works of Laplace and Lagrange (Lagrange 1781; Laplace 1784; see Laskar 2012 for an historic overview). In Laplace–Lagrange (LL) theory, bodies with similar masses are assumed to orbit a central massive body. The Hamiltonian is expanded in terms of the orbital eccentricities and inclinations which are assumed to be small, and non-secular terms are dropped. This method works well for planetary systems, provided that the eccentricities and inclinations are close to zero. However, on long time-scales (after thousands or more secular oscillations), secular chaotic diffusion can cause high eccentricities and inclinations, at which point the expansion is no longer accurate. For example, in the Solar system, the orbit of Mercury is unstable due to secular chaos on a time-scale of ~5 Gyr relative to the current Solar system (Laskar 1994, 2008; Ito & Tanikawa 2002; Laskar & Gastineau 2009). Furthermore, secular chaos can lead to the production of hot Jupiters, and, more generally, play a crucial role in the long-term evolution of planetary systems (Lithwick & Wu 2011, 2014; Wu & Lithwick 2011). Also, in LL theory, the hierarchy is fixed, and more complex configurations such as moons around the planets, or one or more stellar companions to the central star, are not possible.

An alternative method has been developed and applied by Lidov (1962), Kozai (1962) and later by Harrington (1968), Naoz et al. (2013a) and others. In this method, which has been applied to hierarchical triples, the Hamiltonian is expanded in terms of the ratio of the inner to the outer binary separations, which is assumed to be small. A major advantage of this method is that it is valid for arbitrary eccentricities and inclinations, provided that sufficient hierarchy is maintained (i.e. the bodies in the inner and outer binaries are sufficiently separated even at the closest mutual points in their orbits).

Until recently, this approach has been limited to hierarchical triples. An extension to hierarchical quadruples was presented by Hamers et al. (2015), who derived the expanded and orbit-averaged Hamiltonian for both the ‘3+1’ and ‘2+2’ configurations. Here, we present a generalization to hierarchical multiple systems composed of binary orbits, with an arbitrary number of bodies in an arbitrary hierarchy. The main assumptions are as follows.

(i) The system is composed of nested binary orbits (see Fig. 1 for an example quintuple system). Each binary has two ‘children’, which can be either bodies (i.e. point particles) or binaries. If a child is a binary, then its position vector is the centre of mass position vector of all bodies contained within that child. This excludes trapezium-type systems (e.g. Ambartsumian 1954).

(ii) The system is sufficiently hierarchical (see Section 2 for a quantitative definition).

(iii) On short time-scales, the binary orbits are well approximated by bound Kepler orbits (i.e. the time-scales for angular momentum exchange are much longer than the orbital periods).

Although the above assumptions may appear restrictive, it turns out that our method applies to a wide range of astrophysically relevant systems. Integration of the averaged and expanded equations of motion is computationally much less intensive compared to solving the full N-body problem. Therefore, our new method opens up the possibility for studying the long-term dynamics of complex hierarchical systems, without having to resort to costly N-body integrations. Such fast integration is particularly valuable, given the large parameter space involved in these systems.

Moreover, the analytic perturbation method allows for specific effects to be associated with individual terms in the expansion. This allows for a clearer and deeper understanding of the gravitational dynamics compared to direct N-body integration, in which all effects are combined and cannot be disentangled. For example, in hierarchical triples, the octupole-order term, in contrast to the quadrupole-order term, can give rise to orbital flips between prograde and retrograde orbits, potentially leading to very high
2 THE GENERALIZED HAMILTONIAN FOR HIERARCHICAL MULTIPLE SYSTEMS

2.1 Definition and description of the system

We consider hierarchical multiple systems that are composed of nested binaries and which can be represented by 'simplex mobile' diagrams, introduced by Evans (1968). We note that a similar hierarchical decomposition is made in the Kira integrator in STARB (appendix B of Portegies Zwart et al. 2001). An example for a hierarchical quintuple system $N=5$ is given in Fig. 1. The binaries have two 'children', which can be either bodies or binaries themselves. Conversely, each binary or body has a 'parent', with the exception of the unique binary from which all other binaries and bodies originate, i.e. the 'top' binary. Each binary can be assigned a 'level', defined as the number of binaries that need to be traversed in the mobile diagram to reach that binary, counting from the top binary.

Here, we consider only multiple systems with the 'simplex' structure, and not the more general 'multiplex' structure, in which members of the system are allowed to have more than two children (Evans 1968). Note, however, that the structure of most observed hierarchical multiple systems is of the simplex type (e.g. Tokovinin 2014a). This description is similar to that used by Nugeyre & Bouvier (1981).

Mathematically, the structure of the system can be specified in terms of a 'mass ratio matrix' $A$. The components of this $N \times N$-matrix are mass ratios of bodies within the system. The matrix $A$ is defined such that it gives the relation between the absolute position vectors $r$, of bodies in the system and the relative binary separation vectors $r$, (see also Fig. 1). This description is similar to that used by Nugeyre & Bouvier (1981), Walker (1983) and Abad & Docobo (1988). For a precise definition of $A$ and examples, we refer to Appendix A1.

2.2 The expanded Hamiltonian

In Appendix A, we derive, from first principles, the general (Newtonian) Hamiltonian for hierarchical multiple systems as defined above, and we expand it in terms of ratios $x_i$ of separations of binaries at different levels. These ratios are assumed to be small, i.e. we assume that the system is hierarchical. The general expression is comprised of summations over both binaries and bodies, and is therefore not very useful for our purposes. Fortunately, it is possible to rewrite these summations over both binaries and bodies to summations over only binaries, and we carry out this rewriting up to and including fifth order in $x$, where for the highest two orders, $x^5$ and $x^7$, we only include binary pair terms. Our main results, at the various orders, are as follows.

(i) The terms in the Hamiltonian at the lowest order, i.e. first order in $x$, (‘dipole order’), vanish identically for any hierarchical configuration.

(ii) The Hamiltonian at second order in $x$, (‘quadrupole order’) consists of terms which, individually, depend on binary pairs. For each pair, the binaries must be on different levels, and they must also be connected to each other through their children, i.e. the binary with the highest level must be a descendant of the binary with the lowest level. For example, in Fig. 1, the included binary pairs are $(r_1, r_2), (r_2, r_3)$, and $(r_1, r_2)$, whereas pairs $(r_2, r_3)$ and $(r_1, r_1)$ are excluded. The individual binary pair terms are mathematically equivalent to the quadrupole-order terms of the hierarchical three-body Hamiltonian.

(iii) At the ‘octupole order’, i.e. third order in $x$, the Hamiltonian consists of two types of terms.

(a) Terms which, individually, depend on binary pairs, with the binaries at different levels. The pairing occurs similarly as for the quadrupole-order terms. Mathematically, the pairwise terms are equivalent to the octupole-order terms of the hierarchical three-body Hamiltonian.

(b) Terms which, individually, depend on binary triplets, with the binaries at different levels. The triplets to be included are those for which the binary $p$ with the highest level is a ‘descendent’ of the binary with the intermediate level, $u$, and for which $u$ is a descendent of the binary $k$ with the lowest level (cf. equation A103). In other words, all three binaries must be part of the same branch. In Fig. 1, there is only one triplet term, which applies to the binary triplet $(r_1, r_2, r_3)$.

The mathematical form of the individual triplet terms is equivalent to the term depending on three binaries at the octupole order in the hierarchical four-body Hamiltonian $[3^4-1]$ configuration; this term was first derived by Hamers et al. (2015), where it was referred to as a ‘cross term’]. In practice, at least for the type of system considered in this paper, the triplet term can be safely neglected compared to the binary pair terms, even those of higher orders.

(iv) At the ‘hexadecupole order’, i.e. fourth order in $x$, the Hamiltonian consists of three types of terms which depend on binary pairs, triplets and quadlets, respectively. Here, we have restricted to explicitly deriving the binary pair terms only.

(v) At the ‘dotriacontupole order’, i.e. fifth order in $x$, the Hamiltonian consists of four types of terms which depend on binary pairs, triplets, quadlets and quintlets, respectively. As for the hexadecupole order, we have exclusively derived the binary pair terms explicitly.

(vi) Generally, at order $n$ in $x$, there are $n-1$ types of terms. The individual terms depend on at most $n$ binaries. Whether all these terms appear is contingent on the system: if the system does not contain a sufficiently complex hierarchy, then not all different binary terms may appear. For example, in the case of a hierarchical triple, only the binary pair terms appear; a summation with three or more different binaries at high orders does not apply.

In summary, the general hierarchical $N$-body Hamiltonian can be constructed from the Hamiltonians of smaller subsystems. The higher the order, the larger the number of binaries within these subsystems. To lowest non-trivial order, i.e. the quadrupole order, the $N$-body Hamiltonian consists entirely of combinations of three-body (i.e. binary pair) Hamiltonians. In other words, at this order, only the interactions between binary pairs are included.

As we show below (cf. Section 3), the inclusion of high-order binary pair terms is necessary particularly in planetary systems,
where the separation ratios may not be \( \ll 1 \). For example, in the Solar system (including the planets plus Pluto), the mean of the adjacent ratios of semimajor axes (i.e. \( \alpha_{\text{Mercury}}/\alpha_{\text{Venus}}, \alpha_{\text{Venus}}/\alpha_{\text{Earth}} \), etc.) is \( \approx 0.58 \). Good results for this system are obtained only when terms of high orders are included.

2.3 Orbit averaging

After expanding the Hamiltonian in terms of the \( x_i \), we orbit average the Hamiltonian assuming that the motion in each binary on suborbital time-scales is exactly Keplerian (cf. Appendix A5). We employ a vector formalism, where each binary orbit is described by its eccentricity vector, \( e_k \), and \( j_k \). Here, \( j_k \) is the specific angular momentum vector \( \mathbf{h}_k \) normalized to the angular momentum of a circular orbit \( \Lambda_k \), i.e.

\[
j_k \equiv \frac{\mathbf{h}_k}{\Lambda_k}, \quad (1)
\]

where

\[
h_k \equiv r_k \times \mathbf{h}_k, \quad (2)
\]

and

\[
\Lambda_k = M_{k, 1} M_{k, 2} \sqrt{\frac{GM_k}{M_k}}, \quad (3)
\]

We define the mass of binary \( k \), \( M_k \), as the sum of the masses of all bodies contained within the hierarchy of binary \( k \). The masses of the two children of binary \( k \) are denoted with \( M_{k, 1} \) and \( M_{k, 2} \). Evidently, the latter satisfy

\[
M_{k, 1} + M_{k, 2} = M_k. \quad (4)
\]

For example, in Fig. 1, \( M_2 = m_1 + m_2 + m_3 \), \( M_{2, 1} = m_1 + m_2 \) and \( M_{2, 2} = m_3 \). Of course, the choice of which child of binary 2 is ‘child 1’ or ‘child 2’ is arbitrary; the alternative, and equally valid, choice is \( M_{2, 1} = m_3 \) and \( M_{2, 2} = m_1 + m_2 \).

As described in more detail in Appendix A5, the averaging procedure (cf. equation A107) is not a canonical transformation. However, a transformation of the ‘coordinates’ \( e_k \) and \( j_k \) can be found, which leads to a transformed Hamiltonian that is equivalent to the old Hamiltonian, and amounts to averaging the Hamiltonian over the orbits (Naoz et al. 2013a). The transformed coordinates differ from the original ones. However, as noted by Naoz et al. (2013a), the untransformed and the transformed coordinates differ by order \( \chi^2 \). Therefore, this difference can usually be neglected. This is borne out by tests of our algorithm with other methods (cf. Section 3).

Nevertheless, it is important to keep in mind that the orbit-averaged approximation can break down in situations where the time-scale for changes in the (secular) orbital parameters (in particular, the eccentricities) is shorter than the orbital period (Antoniou & Perets 2012; Antonini et al. 2014; Antonini, Murray & Mikkola 2014). In our numerical algorithm (cf. Section 2.5), we check for this condition during the integrations. In the context of planetary systems, the orbit-averaged approximation breaks down when the planets are sufficiently closely spaced for mean motion resonances to be important, which are not taken into account.

We have explicitly derived all orbit-averaged terms up and including octupole order, and including the pairwise hexadecapole- and dotriacontuple-order terms (cf. Appendix A5.2). Furthermore, using complex integration techniques, we have derived a general expression for the averaged pairwise Hamiltonian to order \( n \) in terms of quickly evaluated derivatives of polynomial functions, rather than integrals (cf. Appendix A5.3).

2.4 General implications

2.4.1 Quadrupole order

An immediate implication of Section 2.2 is that to quadrupole order, the qualitative behaviour of the system can be characterized using simple arguments based on the KL time-scales of binary pairs, analogously to the ratio of K.L time-scales that was considered for quadruple systems in Hamers et al. (2015).

An order-of-magnitude estimate of the K.L time-scale \( P_{\text{LK}, p, k} \), \( \tau_{p, k} \), for binaries \( p \) and \( k \) with \( p \) a child of \( k \), can be obtained by dividing \( \Lambda_p \) by the associated order-of-magnitude quadrupole-order term in the orbit-averaged Hamiltonian (cf. equations 17 and A118). This gives

\[
\tau_{p, k} \equiv \frac{M_p}{M_p C_1 M_p C_2} \frac{M_k}{M_k C_1 C_2} \frac{a_k}{a_p} \left( \frac{a_k}{a_p} \right)^2 \left( 1 - e_k^2 \right)^{3/2} \frac{1}{2\pi P_{\text{orb}, p} M_k C_1 C_2}, \quad (5)
\]

where we used equation (3), and the orbital periods \( P_{\text{orb}, p} \) are defined through Kepler’s law,

\[
P_{\text{orb}, k} = 2\pi \sqrt{\frac{a_k^3}{GM_k}}. \quad (6)
\]

In the case of isolated triples, the precise K.L time-scale to quadrupole order (and with the further assumption of highly hierarchical systems) also depends on the initial \( e_p \) and \( \omega_p \) (i.e. the inner orbit eccentricity and argument of pericentre), as well as the relative inclination \( i_{pk} \) between the inner and outer orbits (Kinoshita & Nakai 2007). Formally, we write the K.L time-scale for hierarchical N-body systems as

\[
P_{\text{LK}, p, k} = C(e_p, \omega_p, i_{pk}) \frac{P_{\text{orb}, k}^2}{P_{\text{orb}, p} M_{k, C_1 C_2}} \frac{M_k}{M_p} \left( 1 - e_k^2 \right)^{3/2}. \quad (7)
\]

Here, the dimensionless factor \( C(e_p, \omega_p, i_{pk}) \) captures any dependence on \( e_p, \omega_p \), and \( i_{pk} \); generally, \( C \) is of order unity. For example, for a hierarchical triple system with inner binary masses \( m_1 \) and \( m_2 \) and tertiary mass \( m_3 \), equation (7) reduces to the familiar expression (e.g. Innanen et al. 1997; Kiseleva et al. 1998; Antonini 2015)

\[
P_{\text{LK}, \text{in}, \text{out}} = C(e_{\text{in}}, \omega_{\text{in}}, i_{\text{out}}) \frac{P_{\text{orb}, \text{out}}^2}{P_{\text{orb}, \text{in}}} \frac{m_1 + m_2 + m_3}{m_3} \frac{M_k}{M_p} \frac{a_{\text{out}}}{a_{\text{in}}} \left( 1 - e_{\text{out}}^2 \right)^{3/2}. \quad (8)
\]

The K.L time-scale \( P_{\text{LK}, p, k} \) is a proxy for the strength of the secular torque of orbit \( k \) on orbit \( p \). Therefore, ratios of K.L time-scales applied to different pairs of binaries give a measure for the relative importance of the secular torques.

In the case of three adjacent binaries, \( p, k \), and \( l \), for which \( p \) is a child of \( k \), and \( k \) is a child of \( l \) (i.e. a ‘fully nested’ subsystem, see the left part of Fig. 2), we consider the ratio

\[
\frac{P_{\text{LK}, p, k}}{P_{\text{LK}, k, l}} \approx \frac{C(e_p, \omega_p, i_{pk}) P_{\text{orb}, k}^2}{C(e_k, \omega_k, i_{kl}) P_{\text{orb}, l}^2} \frac{M_k}{M_p} \frac{M_k}{M_l} \left( 1 - e_k^2 \right)^{3/2} \left( 1 - e_l^2 \right)^{3/2}, \quad (9)
\]
In the last line of the expression written in terms of semimajor axes. Note that for quadruple systems, equation (9) reduces to equation (13) of Hamers et al. (2015).

Analogously to the case of fully nested hierarchical quadruple systems (Hamers et al. 2015), the following qualitative behaviour applies.

(i) $\mathcal{R}_{plk}^{(\mathrm{fin})} \ll 1$: the torque of $k$ on $p$ dominates compared to the torque of $l$ on $k$. LK oscillations can be induced by $k$ on $p$. Furthermore, induced precession on $k$ from $p$ can quench LK oscillations in $k$ otherwise induced by $l$.

(ii) $\mathcal{R}_{plk}^{(\mathrm{fin})} \gg 1$: the torque of $l$ on $k$ dominates compared to the torque of $k$ on $p$. LK oscillations can be induced by $l$ on $k$. Effectively, $p$ can be approximated as a point mass.

(iii) $\mathcal{R}_{plk}^{(\mathrm{fin})} \sim 1$: complex, non-regular LK cycles can be induced in $p$; chaotic evolution is possible.

In the case of three binaries, $p$, $k$ and $l$, for which $p$ is a child of $l$, and $k$ is a child of $l$ (i.e. a ‘binary–binary’ subsystem, see the right part of Fig. 2), we consider the ratio

$$
\mathcal{R}_{plk}^{(\mathrm{bb})} = \frac{P_{L,k}}{P_{L,l}} = \frac{C(e_p, \omega_p, i_p)}{C(e_k, \omega_k, i_k)} \left( \frac{a_k}{a_p} \right)^{3/2} \left( \frac{M_p}{M_k} \right)^{3/2}
$$

(note that $M_{\mathrm{CS}(p)} = M_p$ and $M_{\mathrm{CS}(p)} = M_k$).

In this case, the following characteristics apply.

(i) $\mathcal{R}_{plk}^{(\mathrm{bb})} \ll 1$: the torque of $l$ on $p$ dominates compared to the torque of $l$ on $k$. For sufficiently small values of $\mathcal{R}_{plk}^{(\mathrm{bb})}$, $k$ can effectively be treated as a point mass.

(ii) $\mathcal{R}_{plk}^{(\mathrm{bb})} \gg 1$: the torque of $l$ on $k$ dominates compared to the torque of $l$ on $p$. For sufficiently large values of $\mathcal{R}_{plk}^{(\mathrm{bb})}$, $p$ can effectively be treated as a point mass.

(iii) $\mathcal{R}_{plk}^{(\mathrm{bb})} \sim 1$: complex, non-regular LK cycles can be induced in $p$ and $k$ (Pejcha et al. 2013).

### 2.4.2 Higher orders

In hierarchical triple systems, the octupole-order term gives rise to generally more complex, and potentially chaotic eccentricity oscillations compared to when including only the quadrupole-order term, especially if the semimajor axis ratio is small and/or the outer orbit eccentricity is high. Orbital flips can occur between prograde and retrograde orbits, potentially leading to very high eccentricities (Katz et al. 2011; Lithwick & Naoz 2011; Naoz et al. 2013a; Teyssandier et al. 2013; Li et al. 2014a,b). The importance of these effects can be evaluated using the octupole parameter, which is essentially the ratio of the order-of-magnitude estimate of the orbit-averaged octupole-order term to the quadrupole-order term. It is given by (Naoz et al. 2013a)

$$
\epsilon_{\mathrm{oct, triple}} = \frac{|m_1 - m_2| a_{in} e_{out}}{m_1 + m_2 a_{out} (1 - e_{out}^2)}
$$

In the case of hierarchical $N$-body systems, the situation is more complicated because there will generally be more than one pair of binaries, and because at higher orders (starting with the octupole order), terms appear which individually depend on more than two binaries (cf. Section 2.2).

In the applications considered in this paper, the octupole-order triplet terms are found to be negligible compared to the octupole-order binary pair terms, and binary pair terms at higher orders (e.g. Section 3.1). This can be understood by estimating the ratio of the orbit-averaged octupole-order binary triplet term, $\mathcal{S}_{3;2}^{(3;1)}$, to the orbit-averaged octupole-order binary pair term, $\mathcal{S}_{3;2}^{(2;1)}$ (cf. equation A119).

Consider three binaries $p$, $k$ and $l$, where $p \in \{kC\}$, $p \in \{uC\}$ and $u \in \{kC\}$ (i.e. a connected binary triplet in which each binary is on a different level). A distinction should be made when evaluating $\mathcal{S}_{3;2}^{(3;1)}$: we apply it to $(p, u)$ and $(u, k)$ (we do not consider $(p, k)$ because by assumption, $a_p/a_u \gg a_u/a_k$). In the case of $(p, u)$, we find

$$
\mathcal{S}_{3;2}^{(3;1)}(p,u) \sim \frac{e_p}{e_p} \left[ \frac{M_{\mathrm{CS}(p)}}{M_{\mathrm{CS}(p)} - M_{\mathrm{CS}(u)}} \right] \left( \frac{M_p}{M_u} \right) \frac{a_u}{a_p} \frac{1 - e_p^2}{1 - e_u^2}^{3/2}
$$

In the case of $(u, k)$,

$$
\mathcal{S}_{3;2}^{(3;1)}(u,k) \sim \left[ \frac{M_{\mathrm{CS}(u)}}{M_{\mathrm{CS}(p)} - M_{\mathrm{CS}(u)}} \right] \left( \frac{M_{\mathrm{CS}(u)}}{M_{\mathrm{CS}(p)} - M_{\mathrm{CS}(u)}} \right) \left( \frac{M_u}{M_p} \right) \frac{a_u}{a_p} \frac{1 - e_u^2}{1 - e_p^2}^{3/2}
$$

Note that equations (12) and (13) diverge as $M_{\mathrm{CS}(p)} \rightarrow M_{\mathrm{CS}(p)} - M_{\mathrm{CS}(u)} \rightarrow M_{\mathrm{CS}(u)}$ and/or $e_p \rightarrow 0$. In those cases, the corresponding term $\mathcal{S}_{3;2}^{(3;1)}$ vanishes. However, additionally, the binary pair hexadecupole-order term does not vanish (cf. equation A120). Therefore, one should compare to $\mathcal{S}_{3;2}^{(3;1)}$ (this is not done here).

In the case of a planetary system with order Jupiter-mass planets around an order solar-mass star (with the star in the innermost orbit $p$), $M_{\mathrm{CS}(p)} \sim 10^{-3} M_\odot$, $|M_{\mathrm{CS}(p)} - M_{\mathrm{CS}(l)}| \sim 1 M_\odot$, $M_p \sim M_\odot$, $a_p \ll a_l$ and $a_p \gg a_k$ with $a_p/a_l \sim a_k/a_p$. Therefore, the mass ratios in equation (12) are of the order of $10^{-3}$, whereas the semimajor axis ratio is $\ll 1$. Assuming eccentricities close to zero, this shows that the binary triplet term is negligible compared to the binary pair term in the case of $(p, u)$. Similarly, $M_{\mathrm{CS}(u)} \sim 10^{-3} M_\odot$, $|M_{\mathrm{CS}(u)} - M_{\mathrm{CS}(k)}| \sim 1 M_\odot$ and $M_{\mathrm{CS}(u)} \sim M_{\mathrm{CS}(k)}$ (and $M_{\mathrm{CS}(u)} \sim M_{\mathrm{CS}(p)}$). Therefore, a similar conclusion applies in the case of $(u, k)$.

In Appendix A6, we generalize these estimates for nested planetary systems of the importance of terms other than binary pair terms to arbitrary order $n$.

When the non-pairwise binary terms are negligible, it suffices to consider the ratios of binary pair terms at sequential orders. We consider the ratio of the order-of-magnitude orbit-averaged binary pair term at order $n + 1$ to that of order $n$. Using the general expression equation (A136), we find

$$
\mathcal{S}_{n+2;2}^{(n+1;1)}(p,k) \sim \left( \frac{M_p}{M_{\mathrm{CS}(p)} - M_{\mathrm{CS}(u)}} \right) \left( \frac{M_{\mathrm{CS}(p)}}{M_{\mathrm{CS}(p)} - M_{\mathrm{CS}(u)}} \right) \left( \frac{M_p}{M_{\mathrm{CS}(p)} - M_{\mathrm{CS}(u)}} \right) \frac{a_p}{a_k} \frac{1 - e_p^2}{1 - e_k^2}
$$

\[14\]
where \( f_n(e_k) \) is a function of \( e_k \). Based on the expressions in equations (A118), (A119), (A120) and (A121), i.e. for \( n \in \{2, 3, 4, 5\} \),

\[
f_n(e_k) = \begin{cases} 
  e_k, & \text{if } n \text{ even}; \\
  1/e_k, & \text{if } n \text{ odd},
\end{cases}
\]

and we expect that this applies to any \( n \geq 2 \). For \( n = 2 \), equation (14) reads

\[
\frac{\overline{a}_{2;2}}{S_{2;2}} \sim \frac{|M_{p,C1} - M_{p,C2}|}{M_{p,C1} + M_{p,C2}} \frac{a_2}{a_3} \frac{e_k}{1 - e_k^2},
\]

which reduces to equation (11) in the case of a hierarchical triple.

Binary pair terms to high order turn out to be important in multiplanet systems. This is investigated in detail in Section 3.1.

### 2.5 Numerical algorithm

We have developed a numerical algorithm written in C++, SecularMultiple, to efficiently integrate the equations of motion for hierarchical multiple systems based on the formalism described in Section 2, and presented in detail in Appendix A.1 The equations of motion are derived by taking gradients of the orbit-averaged Hamiltonian in terms of the orbital vectors, \( \overline{H} \). Explicitly, the equations of motion are given by the Milankovitch equations (Milankovitch 1939, e.g. Musen 1961; Allan & Ward 1963; Allan & Cook 1964; Breiter & Rataczak 2005; Tremaine, Touma & Namouni 2009; see Rosengren & Scheeres 2014 for a recent overview), i.e.

\[
\frac{d j_k}{d \tau} = -\frac{1}{L_k} [ j_k \times \nabla j_k \overline{H} + e_k \times \nabla e_k \overline{H}] ;
\]

\[
\frac{d e_k}{d \tau} = -\frac{1}{L_k} [ e_k \times \nabla e_k \overline{H} + j_k \times \nabla j_k \overline{H}] .
\]

Here, \( L_k \) is the angular momentum of a circular orbit given by equation (3). The system of first-order differential equations for the sets \( (j_k, e_k) \) for all binaries is solved using the CVODE library (Cohen, Hindmarsh & Dubois 1996).

Our algorithm is interfaced in the AMUSE framework (Pelupessy et al. 2013; Portegies Zwart et al. 2013), and uses the AMUSE particle data model for the user to specify the hierarchical structure and associated parameters in the high-level Python language. Binaries and bodies are both members of a single particle set; the type of particle (body or binary) is specified with a Boolean parameter. The system structure is defined by linking the two children of each binary to other members of the same particle set. We have added support for easily switching between the secular approach and direct N-body integration with any of the direct N-body codes available in AMUSE.

The SecularMultiple algorithm also supports the inclusion of additional forces, including post-Newtonian (PN) terms to the 1PN and 2.5PN orders, and tidal bulges and tidal friction. The PN terms are implemented by treating the binaries in the system as being isolated, and adding the relevant equations for \( e_k \) and \( h_k \). Here, we neglect the contribution of any additional terms which may apply. For example, Naoz et al. (2013b) showed that for hierarchical triples and at the 1PN order, an additional term (an ‘interaction term’) appears that is associated with both inner and outer orbits. Here, we only include the 1PN terms associated with individual binaries (cf. Appendix A7).

To model the effects of tidal bulges and tidal friction, we adopt the equilibrium tide model of Eggleton, Kiseleva & Hut (1998) with a constant tidal time lag \( \tau \) (or, equivalently, a constant viscous timescale \( \tau_k \)). For tidal friction, we adopted the equations derived by Barker & Ogilvie (2009) which are well defined in the limit \( e_k \to 0 \). We implement the equations in binaries where at least one of the children is a body. Here, we treat the ‘companion’ as a point mass, even if the companion is, in reality, a binary. A self-consistent treatment of tides in hierarchical multiple systems is beyond the scope of this work.

As mentioned in Section 2.3, the orbit-averaged approximation breaks down if the time-scale for changes of the angular momentum \( j_k \) is smaller than the orbital time-scale \( \tau_k \). For tidal friction, we allow the user to check for this condition in any binary \( k \) at any time in the integration. Using a root-finding algorithm, the integration is stopped whenever \( t_{j,k} \leq T_{orb,k} \), where \( T_{orb,k} \) is the orbital period of binary \( k \) (cf. equation 6) and \( t_{j,k} \) is the time-scale for the angular momentum of binary \( k \) to change by order itself. The latter is given by

\[
t_{j,k} = \frac{1}{j_k} \frac{d j_k}{d \tau} = \frac{e_k}{1 - e_k^2} \frac{d e_k}{d \tau}^{-1},
\]

where the time derivates are obtained numerically from the equations of motion (cf. equations 17).

3 TESTS: S-TYPE MULTIPLANET SYSTEMS IN SINGLE AND MULTIPLE STELLAR SYSTEMS

3.1 Single-star systems

As a first test and application, we consider single-star multiplanet systems with planets in orbits with small eccentricities and inclinations. This allows for comparison of SecularMultiple with LL theory at relatively low order, i.e. to second order in the eccentricities and the inclinations. The hierarchy of the system is a ‘fully nested’ configuration, and is depicted schematically in Fig. 3. Note that in the framework of the formalism presented in Appendix A,
a multiplanet system can be represented as system in which each planet is assumed to orbit around the centre of mass of the central star plus the planets contained within its orbit. We consider various planet numbers \(N_p\). The mass of the star is assumed to be \(M_\star = 1 \ M_\odot\). For simplicity, the planetary masses, \(m_i\) with \(1 \leq i \leq N_p\), are set equal to \(m_1 = M_1\).

We consider a sequence of systems with different spacing between the planets. The spacing is quantified in terms of \(K_{ij}\), which applies to pairs \((i,j) = (i, i + 1)\) of adjacent planets, and is defined as

\[
K_{ij} \equiv \frac{a_i(1 - e_i) - a_j(1 + e_j)}{R_{Hij}},
\]

where \(R_{Hij}\) is the mutual Hill radius, defined by

\[
R_{Hij} \equiv \frac{a_i + a_j}{2C_{Hij}}; \quad C_{Hij} \equiv \left(\frac{3M_\star}{m_i + m_j}\right)^{1/3}.
\]

For simplicity, we assume a single initial spacing \(K_{ij} = K_0\) for adjacent planets. Furthermore, we choose a single initial eccentricity of \(e_i = 0.01\). With these assumptions and with the innermost semimajor axis \(a_1\) specified, equation (19) defines the semimajor axes of an \(N_p\)-planet system with constant semimajor axis ratios. For reference, we show in Fig. 4 the relation between the semimajor axis ratio \(a_i/a_j\) and \(K_0\) according to equation (19).

The initial inclinations are \(i_i = 1^\circ\), where the \(i_i\) are measured with respect to an arbitrary inertial reference frame. The longitudes of the ascending node, \(\Omega_i\), are chosen randomly from a uniform distribution. Note that this implies that the orbits of the planets are (slightly) mutually inclined. The arguments of pericentre \(\omega_i\) are also sampled randomly from a uniform distribution. Because the latter mainly affect the phases of the secular oscillations in the orbital elements, only a single realization of \(\omega_i\) is taken for each sequence in \(K_0\). For \(\Omega_i\), five different values are sampled for each \(K_0\), and results are averaged over the integrations with different \(\Omega_i\).

For the fixed parameters, we integrated a sequence of systems with different \(K_{ij} = K_0\), \(\Omega_i\), and \(N_p\). In Fig. 5, we show an example for \(K_0 = 12\) and \(N_p = 4\); the lines show the eccentricities (top panel) and the inclinations (bottom panel) of the planets as a function of time. Solid lines are according to \texttt{SECULARMULTIPLE} with the inclusion of all terms up and including octupole order, plus the hexadecupole and dotriacontupole binary pair terms. Dashed lines are according to second-order LL theory. Lines with different colours correspond to the four planets (see the legend).

Figure 4. The relation between the semimajor axis ratio \(a_i/a_j\) and \(K_{ij} = K_0\) according to equation (19). Assumed parameters are \(M_\star = 1 \ M_\odot\), \(m_i = 1 \ M_1\) and \(e_i = 0.01\).

Figure 5. The eccentricities (top panel) and inclinations (bottom panel) as a function of time for a four-planet system with spacing \(K_0 = 12\) (cf. equation 19). The initial eccentricities are \(e_i = 0.01\) and inclinations \(i_i = 1^\circ\). Solid lines are according to \texttt{SECULARMULTIPLE} with all terms up including octupole order, plus the hexadecupole and dotriacontupole binary pair terms. Dashed lines are according to second-order LL theory. Lines with different colours correspond to the four planets (see the legend).
Figure 6. As in Fig. 5, now showing the innermost planet’s eccentricity and inclination according to LL theory (dashed lines), and SECULARMULTIPLE with inclusion of various terms (see the legend). Agreement of SECULARMULTIPLE with LL theory increases as higher order terms are included.

Generally, increasing $K_0$ implies smaller semimajor axis ratios, which improves the agreement of SECULARMULTIPLE with LL theory. To study this more quantitatively, and to determine how small $K_0$ can be chosen for still acceptable agreement, we show in Fig. 7 comparisons between SECULARMULTIPLE and LL theory, assuming $N_p = 3$. On the horizontal axes, $K_0$ is plotted, whereas the vertical axes show various quantitative measures for this agreement. In the top two panels of Fig. 7, we consider the fractional differences between the methods, of the amplitudes of the eccentricity oscillations (upper panel) and of the peak frequencies of the power spectra of the eccentricity oscillations (lower panel). Here, the solid lines represent the mean values of these measures of all planets; error bars show the standard deviations. In the middle two panels of Fig. 7, we consider similar differences, now applied to oscillations of the inclinations. Lastly, in the bottom two panels of Fig. 7, we consider the time-averaged relative differences between the eccentricities (upper panel) and the inclinations (bottom panel).

In all cases, there is no discernable difference between the inclusion of the octupole-order binary pair terms and the inclusion of all octupole-order terms (i.e. including the binary triplet terms); in Fig. 7, the corresponding curves always overlap. When considering the amplitude of the eccentricity oscillations, the octupole-order terms, surprisingly, give better agreement with LL theory compared to the case of including the next higher order terms, the hexadecupole-order terms. However, the amplitude of the inclination oscillations tends to be better with the inclusion of the hexadecupole-order terms. Also, when considering the time-averaged measure (bottom two panels of Fig. 7), including the hexadecupole-order terms also performs better compared to the octupole-order terms only. Note that for the inclination oscillations, there are little to no differences between the hexadecupole- and dotriacontupole-order terms. In contrast, the agreement with respect to eccentricity is typically much better when including dotriacontupole-order terms.

Figure 7. Quantitative measures of agreement between SECULARMULTIPLE (with various terms, indicated in the legends) and LL theory, assuming $N_p = 3$. In the top two panels, we consider the fractional differences between the methods, of the amplitudes of the eccentricity oscillations (upper panel) and of the peak frequencies of the power spectra of the eccentricity oscillations (lower panel). Here, the solid lines represent the mean values of these measures of all planets; error bars show the standard deviations. In the middle two panels, we consider similar differences, now applied to the oscillations of the inclinations. Lastly, in the bottom two panels, we consider the time-averaged relative differences between the eccentricities (upper panel) and the inclinations (bottom panel).
Hierarchical N-tuple systems

Figure 8. Quantitative measures of agreement between \textsc{secularmultiple} and LL theory as in Fig. 7, now with four planets. Here, we only show the time-averaged relative differences between the eccentricities (upper panel) and the inclinations (bottom panel).

Figure 9. Quantitative measures of agreement between \textsc{secularmultiple} and LL theory as in Fig. 8, now with five planets.

In Figs 8 and 9, we show similar figures (only considering the time-averaged measure) for $N_p = 4$ and 5, respectively. The trends described above for $N_p = 3$ also apply to larger planet numbers. As the number of planets is increased, the dependence of the measure of agreement as a function of $K_0$ becomes smoother.

Generally, $\sim 2$ per cent discrepancy with respect to LL theory (in terms of the time-averaged measure) is reached with dotriacontupole-order terms if $K_0 \gtrsim 10$. When including only the octupole-order terms, the discrepancy is between $\sim 10$ and $\sim 20$ per cent, depending on the number of planets. In particular, the agreement with respect to the eccentricity becomes much better with the inclusion of the dotriacontupole-order terms. This demonstrates the need to include high-order terms in multiplanet systems.

3.2 Binary-star systems

As mentioned in Section 1, it is possible that a star hosting a multiplanet system is itself part of a multiple stellar system. Here, we consider the case of an S-type multiplanet system in which the host star has a more distant stellar binary companion well beyond the orbits of the planets. A general representation of the system (for $N_p$ planets) is given in Fig. 10. In Section 3.2, we also consider the planet-hosting star to be the tertiary star in a stellar triple system. In the latter case, the stellar ‘binary companion’ to the planet-hosting star is itself a stellar binary (cf. Fig. 21).

3.2.1 Two-planet system in a stellar binary – comparison with direct N-body integrations

First, we compare results of \textsc{secularmultiple} to a number of direct N-body integrations of a system previously studied by Takeda et al. (2008). The latter authors considered two-planet systems, and showed that two distinct dynamical classes exist with respect to the response of the multiplanet system to the secular torque of the binary companion. In one class, the orbits of the planets evolve ‘rigidly’, i.e. closely maintaining their mutual inclinations and nodal angles despite an overall change of the orbital plane of the multiplanet system. In the second class, the orbits are coupled to the secular torque of the binary companion, thereby inducing potentially large mutual inclinations between the planets and large excitations of the eccentricities.

In Figs 11 and 12, we show two integrations similar to figs 5 and 6 of Takeda et al. (2008), respectively (refer to the captions for detailed parameters). In these figures, the planets are either decoupled from each other and respond to the secular torque of the binary companion (Fig. 11, with $m_2 = 0.032 M_J$) or are weakly coupled (Fig. 12, $m_2 = 0.32 M_J$).

For verification purposes,\footnote{We were unable to obtain the data from Takeda et al. (2008).} we carried out a number of direct N-body integrations of these systems with various codes within AMUSE: \textsc{hermite} (Hut, Makino & McMillan 1995), \textsc{mikkola} (Mikkola & Merritt 2008), \textsc{huayno} (Pelupessy, Jänes & Portegies Zwart 2012) and \textsc{sakura} (Gonçalves Ferrari, Boekholt & Portegies Zwart 2014). In Figs 13 and 14, we show, for $m_2 = 0.032 M_J$ and $m_2 = 0.32 M_J$ respectively, the energy errors, the semimajor axes and the eccentricities of the planets for the integrations with these codes. We also include integrations with \textsc{secularmultiple} (black...
Figure 11. Integration of a two-planet system with a stellar binary companion (cf. Fig. 10). The system parameters are adopted from fig. 5 of Takeda et al. (2008). The planetary parameters are $m_1 = 1 M_J$, $a_1 = 2$ au, $e_1 = 0.01$, $i_1 = 50^\circ$, $\omega_1 = 0^\circ$, $\Omega_1 = 0^\circ$ (inner planet; solid black lines), and $m_2 = 0.032 M_J$, $a_2 = 31.6$ au, $e_2 = 0.01$, $i_2 = 50^\circ$, $\omega_2 = 0^\circ$, $\Omega_2 = 0^\circ$ (outer planet; red dashed lines). The central star has mass $M_\star = 1 M_\odot$, and the binary companion, with mass $M_{\text{bin}} = 1 M_\odot$, is in an orbit with $a_{\text{out}} = 750$ au, $e_{\text{out}} = 0.2$, $i_{\text{out}} = 0^\circ$, $\omega_{\text{out}} = 0^\circ$ and $\Omega_{\text{out}} = 0^\circ$, i.e. the initial mutual inclination between the planetary orbits and the binary orbit is $50^\circ$. In the third panel, the blue dotted line shows the mutual inclination $i_{12}$ between the two planets; note the different scale on the vertical axis, indicated to the right of the panel.

Figure 12. As in Fig. 11, now with $m_2 = 0.32 M_J$ (parameters adopted from fig. 6 of Takeda et al. 2008).

Figure 13. Comparison between secularmultiple and various direct N-body integrations using different codes (refer to the labels in the top panel) for the system from Fig. 11 ($m_2 = 0.032 M_J$). Top panel: the energy errors; middle panel: the semimajor axes of the planets (by construction, these remain exactly constant in secularmultiple). Bottom panel: the eccentricities of the planets.

Figure 14. As in Fig. 13, now with $m_2 = 0.32 M_J$.

For hermite and huayno, the energy errors increased to $O(10^{-1})$ and $O(10^{-2})$, respectively, and the semimajor axes of the planets started to deviate significantly from their original values (cf. the middle panels of Figs 13 and 14). Given the large energy errors and the differences in behaviour in the innermost planet semimajor axis evolution between hermite and huayno (according to the former, $a_1$ decreases over several 100 Myr, whereas according to the...
two direct codes MIKKOLA and SAKURA. For \( m_2 = 0.032 M_J \), there is a relatively larger discrepancy in \( e_1 \) between SEcularMULTIPLE and MIKKOLA of \( \approx 0.02 \) at \( \approx 40 \) Myr. However, SEcularMULTIPLE and SAKURA agree very well. In contrast to MIKKOLA, SAKURA and SECULARMULTIPLE, HERMITE and HUAYNO give a very different evolution of \( e_1 \), and this is likely due to the large energy errors in the integrations with the latter codes.

We conclude that there is good agreement of SEcularMULTIPLE with the most accurate direct \( N \)-body integrations. We emphasize that HERMITE and HUAYNO, even though slower compared to SEcularMULTIPLE by a factor of \( \sim 10^5 \), fail to accurately produce the eccentricity evolution of the innermost planet. To get accurate results on secular time-scales with direct \( N \)-body methods, it is crucial that energy errors remain small during the evolution (based on Fig. 13, no larger than \( \sim 10^{-5} \)). Note that this minimum energy error is smaller than the value of \( 10^{-1} \) suggested by Boekholt & Portegies Zwart (2015); however, this value applies in a statistical sense to an ensemble of systems, and not to individual systems. This requires the use of special integration techniques such as algorithm chain regularization (as in MIKKOLA) or Keplerian-based Hamiltonian splitting (as in SAKURA). Alternatively, for the hierarchical systems considered here, SEcularMULTIPLE agrees well with the most accurate direct \( N \)-body codes, and it is faster by several orders of magnitude.

In Section 3.2.2 below, we take advantage of the speed of SEcularMULTIPLE, and study more generally the nature of the eccentricity oscillations as a function of the binary semimajor axis.

### 3.2.2 Four-planet system with constant spacing in a stellar binary

Here, we consider four-planet systems with fixed spacing and small initial eccentricities and inclinations as in Section 3.1, now including a binary companion star with mass \( M_{\text{bin}} = 1 M_{\odot} \). For the multiplanet system, we set \( M_{3,4} = 1 M_{\odot} \), \( m_1 = 1 M_J \), \( K_0 = 10 \), \( a_1 = 0.2 \) au, \( e_1 = 0.01 \) and \( i_1 = 1^\circ \). A range of semimajor axes for the binary companion orbit \( a_{\text{out}} \) is assumed: between 50 and 150 au with \( e_{\text{out}} = 0.1 \), and between 100 and 300 au with \( e_{\text{out}} = 0.8 \). The lower limits on \( a_{\text{out}} \) are chosen to ensure short-term dynamical stability according to the formulae of Holman & Wiegert (1999). The initial inclination of the binary orbit is set to \( 80^\circ \) with \( \Omega_{\text{out}} = \omega_{\text{out}} = 0^\circ \). For the two values of \( e_{\text{out}} \), we integrated 500 systems with 100 different values of \( a_{\text{out}} \), and for each value of \( a_{\text{out}} \), five realizations of \( \Omega_\) for the planetary system assuming that the \( \Omega_\) are randomly distributed. Because the planetary inclinations are small, the initial mutual inclinations of the planets with respect to the binary companion are very similar to each other, and are \( \approx 80^\circ \). We integrate each system for a duration of 1 Myr, which is comparable to the LK time-scale of the binary with respect to the outermost planet.

In the top panel of Fig. 17, we show the resulting maximum values of the eccentricities of the planets as a function of \( a_{\text{out}} \), assuming \( e_{\text{out}} = 0.1 \). Bullets show the average values over \( \Omega_\), whereas the error bars indicate the standard deviations. In the bottom panel of Fig. 17, we show the mean values of all combinations of the mutual inclinations between the planets, averaged over time. Similar results are shown, for \( e_{\text{out}} = 0.8 \), in Fig. 18.

For large \( a_{\text{out}} \), the maximum eccentricities are small and so are the mutual inclinations. In this limit, the secular torque of the binary companion is weak compared to the mutual torques exerted by the planets. Although the absolute inclinations and longitudes of

---

\footnote{We use the subscript ‘out’ rather than e.g. ‘bin’, in anticipation of the case of a triple-star system discussed in Section 3.3.}
As \( a_{\text{out}} \) is decreased, the torque of the binary companion increases. For sufficiently small \( a_{\text{out}} \), the outermost planet is decoupled from the inner planets resulting in larger mutual inclinations; the outermost planet reaches high eccentricity. For \( a_{\text{out}} \lesssim 75 \text{ au} \), \( e_4 \) is high enough for planet 4 to cross its orbit with planet 3; consequently, we stopped the integration. These systems are not included in Fig. 17.

The maximum eccentricities of planets 1 through 3, in particular planet 3, are also affected when decreasing \( a_{\text{out}} \). In our systems, however, they do not reach high enough values for orbit crossings to occur. In Fig. 20, we show an example of the time evolution with \( a_{\text{out}} \approx 80.3 \text{ au} \) and \( e_{\text{out}} = 0.1 \). The outermost two planets are markedly affected by LK cycles induced by the binary companion. For planet 3, secular oscillations due to planet–planet torques, which have shorter time-scales compared to the LK oscillations, are still clearly present. Note that even though the eccentricity of the outermost planet is strongly increased by the binary companion, the mutual inclination with respect to planet 1 (cf. the green dotted line in the bottom panel of Fig. 19) remains small, i.e. \( \lesssim 5^\circ \!).

To estimate the value of \( a_{\text{out}} \) that separates the two regimes, we use the arguments given by Takeda et al. (2008). We estimate the LK time-scale \( t_{\text{LK}} \) (cf. equation 7) of the binary companion with respect to the outermost orbit by

\[
t_{\text{LK}} \approx \frac{1}{3\pi} \left( \frac{P_{\text{orb, out}}^2}{P_{\text{orb, bin}}^2} \right) \frac{M_{*,1} + M_{*,3}}{M_{*,\text{out}}} (1 - e_{\text{out}}^2)^{3/2}.
\]

We compare \( 2t_{\text{LK}} \), the approximate time-scale for nodal precession due to the secular torque of the binary companion, to \( t_{\text{LK}, p4} \equiv 2\pi/f_4 \), an estimate of the time-scale associated with nodal oscillation of the fourth planet according to second-order LL theory (Murray & Dermott 1999).

In Fig. 17, we show with the black solid lines the ratio \( 2t_{\text{LK}}/t_{\text{LK}, p4} \) as a function of \( a_{\text{out}} \). The vertical dotted lines indicate the value of \( a_{\text{out}} \) for which the ratio is \( \approx 1 \). The latter lines indeed approximate the transition between the LK-dominated and planet–planet-dominated regimes.

In Fig. 18, we show a similar figure of the maximum eccentricities and averaged inclinations as a function of \( e_{\text{out}} \), now with \( e_{\text{out}} = 0.8 \). The behaviour of the maximum eccentricities and the averaged mutual inclinations as a function of \( a_{\text{out}} \) is similar as for the case \( e_{\text{out}} = 0.1 \). As expected, the transition occurs at larger \( a_{\text{out}} \), i.e. \( a_{\text{out}} \gtrsim 150 \text{ au} \) compared to \( \approx 90 \text{ au} \) if \( e_{\text{out}} = 0.1 \). The method of comparing \( 2t_{\text{LK}} \) to \( t_{\text{LK}, p4} \) again gives an estimate for the transition value of \( a_{\text{out}} \).

### 3.3 Triple-star systems

To our knowledge, the secular dynamics of multiplanet systems orbited by a stellar binary have not been explored. Here, we carry out a number of integrations similar to those of Section 3.2.2, but now with the binary companion star replaced by a stellar binary with semimajor axis \( a_{\text{bin}} \). The hierarchy of the system is shown in a mobile diagram in Fig. 21. The system can be viewed as a stellar hierarchical triple system, in which the tertiary star has four S-type planets (effectively making it a heptuple system).

In order to easily compare with the case of a stellar binary, we assume that the sum of the inner binary stellar masses is equal to the mass of the companion star, \( M_{*,2} = M_{*,3} = M_{*,\text{bin}} \). That was assumed in Section 3.2.2, i.e. \( M_{*,2} + M_{*,3} = M_{*,\text{bin}} \). Here, we set

![Figure 17.](image1)

The maximum eccentricities of the planets as a function of \( e_{\text{out}} \), assuming \( e_{\text{out}} = 0.1 \). Bullets show the average values over \( \Omega_4 \), whereas the error bars indicate the standard deviations. In the bottom panel, we show the mean values of all combinations of mutual inclinations between the planets, averaged over time. In each panel, the right axes show the logarithm of the ratio \( 2\pi_4/\Omega_4 \), where \( \pi_4 \approx 2\pi/f_4 \), of the nodal precession time-scale associated with LK oscillations induced by the binary companion, compared to the nodal precession time-scale associated with the mutual planetary torques.

![Figure 18.](image2)

Similar to Fig. 17, now with \( e_{\text{out}} = 0.8 \).
$M_{+,2} = 0.6 \, M_\odot$ and $M_{+,3} = 0.4 \, M_\odot$. The initial (absolute) inclination of the inner orbit is set to $i_{in} = 0^\circ$; for the outer orbit, we set $i_{out} = 80^\circ$. Furthermore, $\Omega_{in} = \Omega_{out} = \omega_{in} = \omega_{out} = 0^\circ$. Consequently, the mutual inclinations between the multoplanet system and the outer orbit are $\approx 80^\circ$ as in Section 3.2.2, and the inner and outer binaries are inclined by $80^\circ$. The initial eccentricities of the stellar orbits are $e_{in} = e_{out} = 0.1$. We integrated a grid of systems with various values of $a_{in}$ and $a_{out}$. As in Sections 3.1 and 3.2, for each combination of parameters, five integrations were carried out with all parameters fixed, except for the $\Omega_i$ of the planets, which were sampled randomly.

In Fig. 22, we show the maximum eccentricities (top panel) and the time-averaged mutual inclinations (bottom panel) of the planets as a function of $a_{in}$, with fixed $a_{out}$ = 80 au and $e_{out}$ = 0.1. Note that in the equivalent system with the inner binary replaced by a point mass, the maximum eccentricities are approximately 0.02, 0.02, 0.05 and 0.27 for planets 1 through 4, respectively (see e.g. Fig. 20). These values are indeed attained for small values of $a_{in}$, i.e. $a_{in} \lesssim 3$ au, in which case the inner binary is effectively a point mass. However, for $a_{in} \gtrsim 3$ au, the maximum eccentricities are strongly affected.

For large $a_{in}$, $a_{in} \gtrsim 10$ au, the maximum eccentricities are smaller compared to the case of a stellar binary. This can be understood by considering the evolution of the nodal angle $\Omega_{out}$ of the outer binary. An example of the evolution of the eccentricities, inclinations and nodal angles assuming $a_{in} \approx 14.0$ au, $a_{out} \approx 80.0$ au and $e_{out} = 0.1$ is shown in Fig. 23. In the case of a stellar binary, $\Omega_{out}$ does not oscillate because the planets are not massive enough to cause precession of the angular momentum vector of the outer binary, $h_{out}$. However, in the case of a stellar triple with sufficiently large $a_{in}$, the inner binary causes a precession of $h_{out}$ on a time-scale $2\kappa_{K,in, out}$. In the case shown in Fig. 23, the time-scale for oscillations of $\Omega_{out}$ is short compared to the time-scale of LK oscillations of the outer orbit on the outermost planet (cf. Fig. 20). Consequently, the rapid nodal precession of $\Omega_{out}$ reduces the excitation of planetary eccentricities by the secular torque of the outer binary.

However, the opposite effect can occur if the nodal precession time-scale of the inner and outer binaries, $2\kappa_{K,in, out}$, is similar to the time-scale $t_{2,3 \omega}$ for precession of the outermost planet nodal angle due to the planet–planet torques. In this case, the (nearly) synchronous nodal precession frequencies of the outer binary and the outermost planets cause an additional excitation of the eccentricity oscillations of the innermost planets, compared to the case of a stellar binary. An example is shown in Fig. 24, in which $a_{in} \approx 9.0$ au, $a_{out} \approx 80.0$ au and $e_{out} = 0.1$ are assumed. The eccentricity of the outermost planet, planet 4, is excited to large values; in particular, it evolves in an intricate manner on a time-scale of approximately twice the time-scale of the eccentricity oscillations of the inner binary. The latter indeed occur on time-scales of half the nodal oscillation...
the maximum eccentricities (top panel) and time-averaged mutual inclinations (bottom panel) of the planets as a function of $a_{in}$, with fixed $a_{out} = 80$ au and $e_{out} = 0.1$. Each bullet corresponds to five different realisations with respect to $/Omega_1$ of the planets; the bullets (error bars) indicate the mean values (standard deviations). In the top panel, the black solid line shows the ratio $R$ (right axis) of the nodal precession time-scale associated with the outermost planet due to planet–planet torques, to the nodal time-scale associated with inner–outer binary torques. Black vertical dotted lines show values of $a_{in}$ corresponding to various integer ratio values of $R$, indicated in the top panel. The red hatched region shows the values of $a_{in}$ for which the orbit of the fourth planet is sufficiently eccentric to cross with that of the third planet.

In this regime of excitation of the planetary eccentricities coupled to the LK oscillations of the inner and outer stellar binaries, high values of the planetary eccentricities can be reached. For example, in Fig. 22, for $7 \lesssim a_{in}/$au $\lesssim 8$, $e_4$ becomes large enough for orbit crossing with planet 3 (indicated with the red hatched region). In the right axis in the top panel of Fig. 22, we show with the solid black line the ratio $R$ of the nodal precession time-scale associated with the outermost planet due to planet–planet torques, to the nodal time-scale associated with the inner–outer binary torques. Note that the latter cause oscillations in $/Omega_1$ and $/Omega_{out}$ on the same time-scale (see e.g. Fig. 24). Vertical dashed lines indicate values of $a_{in}$ for which $R$ is equal to various integer ratios. The strongest excitations, likely leading to a destabilization of the planetary system, occur when $R \sim 1$. Weaker excitations occur near other integer ratios.

In Figs 25 and 26, we show two figures similar to Fig. 22 with the maximum eccentricities and time-averaged mutual inclinations as a function of $a_{in}$, for $a_{out} \approx 85.0$ au and $a_{out} \approx 90.0$ au, respectively. For $a_{out} \approx 85.0$ au, there is a mild excitation of $e_4$ in the case of a stellar binary, with $e_{max,4} \approx 0.04$ (cf. Fig. 17). However, in the case of a stellar triple, large values of $e_4$ can be reached, even leading to orbit crossings, if $R \sim 1$. Interestingly, there is a high and wide peak in $e_{max,4}$ near $R = 2/3$; this is not the case for $a_{out} \approx 80.0$ au (cf. the top panel of Fig. 22). For $a_{out} \approx 90.0$ au (cf. Fig. 26), there is no strong excitation of $e_4$ in the case of a stellar binary (cf. the bottom panel of Fig. 24). Also, the inclination, of the outermost planet in particular, is strongly excited, reaching values as high as $\approx 30^\circ$ with respect to planet 1 (cf. the green dotted line in the middle panel of Fig. 24).

In Figs 25 and 26, we show two figures similar to Fig. 22 with the maximum eccentricities and time-averaged mutual inclinations as a function of $a_{in}$, for $a_{out} \approx 85.0$ au and $a_{out} \approx 90.0$ au, respectively. For $a_{out} \approx 85.0$ au, there is a mild excitation of $e_4$ in the case of a stellar binary, with $e_{max,4} \approx 0.04$ (cf. Fig. 17). However, in the case of a stellar triple, large values of $e_4$ can be reached, even leading to orbit crossings, if $R \sim 1$. Interestingly, there is a high and wide peak in $e_{max,4}$ near $R = 2/3$; this is not the case for $a_{out} \approx 80.0$ au (cf. the top panel of Fig. 22). For $a_{out} \approx 90.0$ au (cf. Fig. 26), there is no strong excitation of $e_4$ in the case of a stellar binary (cf. the bottom panel of Fig. 24). Also, the inclination, of the outermost planet in particular, is strongly excited, reaching values as high as $\approx 30^\circ$ with respect to planet 1 (cf. the green dotted line in the middle panel of Fig. 24).
Figure 25. Similar to Fig. 22, now assuming $a_{\text{out}} = 85$ au and $e_{\text{out}} = 0.1$.

Figure 26. Similar to Fig. 22, now assuming $a_{\text{out}} = 90$ au and $e_{\text{out}} = 0.1$.

In the case of a stellar triple, excitation is still possible if $R \sim 1$.

Generally, the locations and relative heights of the peaks with respect to $R$ change with different parameters of the stellar binary orbit. Further investigation into this behaviour is left for future work. Nevertheless, the results found here already suggest that compared to the case of a single stellar companion, the ‘binary nature’ of the companion in the case of a stellar triple can result in both dynamical protection and destabilization of the planets against the stellar torques, depending on the parameters. Given that destabilization only occurs for specific values of the ratio $R$ whereas protection occurs in the other cases, we expect that the typical effect is that of protection.

4 SECULAR CONSTRAINTS IN OBSERVED SYSTEMS

4.1 30 Arietis

30 Arietis (commonly abbreviated as 30 Ari) is a ‘2+2’ quadruple star system consisting of F-type main-sequence stars, with an age of $\approx 0.9$ Gyr (Guenther et al. 2009). The subsystem 30 Ari A is a spectroscopic binary with a period of 1.109 526 d and an eccentricity of 0.062 (Morbey & Brosterhus 1974). This subsystem forms a visual binary, with a period of $\approx 34 000$ yr, with a subsystem containing 30 Ari B, an F6V star (Tokovinin et al. 2006). The latter star harbours 30 Ari Bb, a massive planet ($m_{\text{sin}} i \approx 9.88 M_J$) orbiting 30 Ari B in $\approx 335$ d with an eccentricity of 0.289 (Guenther et al. 2009). Recently, Riddle et al. (2015) found an $\approx 0.5 M_\odot$ companion star to 30 Ari B, 30 Ari C, in an orbit with a projected separation of $\approx 22.3$ au (Roberts et al. 2015). In Fig. 27, we show, in a mobile diagram, the hierarchy of the system, which is effectively a hierarchical quintuple system. To date, 30 Ari is the second confirmed stellar quadruple system known to host at least one exoplanet; the first is Ph1b (Schwamb et al. 2013).

Apart from the masses of the components and (most of) the semi-major axes and eccentricities, the orbital properties of 30 Ari, in particular the relative inclinations, are unknown. Here, we investigate the secular dynamical evolution of the system, focusing on the orbit of the planet 30 Ari Bb (Section 4.1.1). Using secular stability arguments, we constrain the relative inclinations. Furthermore, we investigate the possibility of additional planets around 30 Ari B (Section 4.1.2).

Our assumed parameters are listed in Table 1. For 30 Ari C (i.e. orbit b$_1$), only the projected separation of 22.3 au is known. Here, we...
adopt a semimajor axis of $a_{b_1} = 22.3$ au, and consider a distribution of different eccentricities (see below).

First, we consider the importance of orbit $b_1$ with regard to the secular evolution of orbit $b_3$ and its constituents. As shown in Section 2.4, this can be estimated by considering the ratio $\mathcal{R}^{(bb)}_{b_1,b_2,b_3}$ of the LK time-scale for the $(b_1, b_3)$ pair, compared to that for the $(b_2, b_3)$ pair. Setting the coefficients $C$ in equation (10) equal to unity for simplicity, this ratio is given by

$$
\mathcal{R}^{(bb)}_{b_1,b_2,b_3} \approx \left( \frac{a_{b_2}}{a_{b_1}} \right)^{3/2} \left( \frac{M_{b_1}}{M_{b_2}} \right)^{3/2} 
\approx \left( \frac{2.4 \times 10^{-2} \text{ au}}{22.3 \text{ au}} \right)^{3/2} \left( \frac{1.63 M_\odot}{1.45 M_\odot} \right)^{3/2} \approx 4.1 \times 10^{-5},
$$

which is $\ll 1$. This shows that binary $b_2$, i.e. the 30 Ari A spectroscopic binary, is effectively a point mass from a secular dynamical point of view. Nevertheless, in the numerical integrations below, we do not make this approximation, i.e. we resolve all secular interactions.

### 4.1.1 Single planet

We carried out an ensemble of integrations of 5000 systems in which the unknown orbital parameters were sampled from assumed distributions. In particular, $e_{b_1}$ and $e_{b_2}$ were sampled from a Rayleigh distribution $dn/deg \propto e_i \exp(-\beta e_i^2)$ with $(e_i)^{1/2} = \beta^{-1/2} = 0.3$ (Raghavan et al. 2010) in the range $0.01 < e_{b_2} < 0.8$ and $0.01 < e_{b_2} < 0.9$. The upper limit on $e_{b_1}$ is motivated by the requirement of (short-term) dynamical stability of the planet with respect to orbit $b_1$. Using the formulae of Holman & Wiegert (1999), we find that the maximum value of $e_{b_1}$ such that the planet in an S-type orbit around 30 Ari B is stable against the perturbation of 30 Ari C is $\approx 0.80$. The upper limit on $e_{b_2}$ is motivated by the requirement of (short-term) dynamical stability of orbit $b_2$ with respect to orbit $b_1$. Using the stability criterion on Mardling & Aarseth (2001), we find that the largest value of $e_{b_2}$ for dynamical stability is $\approx 0.90$. The inclinations of all orbits were sampled from a distribution that is linear in $\cos (i)$. The arguments of pericentre $\omega_1$ and the longitudes of the ascending nodes $\Omega_1$ were sampled assuming random distributions.

We integrated the systems for a duration of $t_{\text{end}} = 1$ Gyr. We also included precession due to relativity in all orbits (cf. Appendix A7) and precession due to tidal and rotational bulges in the planet (cf. Section 2.5). For the planet, we assumed an apsidal motion constant of $\kappa_{\text{Ap}} = 0.52$ and a spin frequency of $1 \text{ d}^{-1}$, with the spin vector initially aligned with binary $p_1$. Tidal dissipation in the planet was not included in detail; instead, we assumed that strong tidal dissipation would occur as soon as the pericentre of the orbit of the planet reached a value smaller than $3 R_\odot$. In this case, we considered the system to be unstable, in the sense that the semimajor axis of the planet would decrease to a smaller value compared to the observed value. Furthermore, we considered a realization to be unstable if the eccentricities of any of the orbits would imply orbit crossing.

In Fig. 28, we show in the $(i_{p_1-b_1}, i_{b_1-b_3})$-plane the systems that remained stable (green bullets) and those that became unstable (red crosses). Distributions of these quantities for the two cases are shown in the top and right insets, respectively. There is a strong dependence of instability on $i_{p_1-b_1}$, with instability occurring between

### Figure 28. Outcomes of integrations of Monte Carlo realizations of 30 Ari in the $(i_{p_1-b_1}, i_{b_1-b_3})$-plane. Systems that are stable (unstable) are shown by green bullets (red crosses). The insets show distributions of these quantities for these two cases with green and red lines, respectively.
is a clear dependence of $e_{\text{max},b_1}$ on $i_{p_1-b_1}$, with excitations of $e_{\text{b}_1}$ reaching $\approx 0.8$ if $i_{p_1-b_1}$ is around $50^\circ$ or $130^\circ$; note that $e_{\text{b}_1} = 0.8$ is close to the limit of dynamical stability. This dependence can be understood by noting that orbit $p_1$ can induce precession on orbit $b_1$, reducing the amplitude of eccentricity oscillations in $b_1$ (this effect was discussed previously in Hamers et al. 2015). The torque of orbit $p_1$ on $b_1$ is weakest when $p_1$ and $b_1$ are inclined by $\sim 50$ or $130^\circ$. Therefore, $e_{\text{max},b_1}$ shows a maximum near these values.

To understand this more quantitatively, we show in the bottom panel of Fig. 29 with the dashed lines semi-analytic calculations of the maximum eccentricity in orbit $b_1$ as a function of $i_{p_1-b_1}$ for various values of $i_{b_1-b_2}$, using a method similar to that of Hamers et al. (2015). Note that for $50^\circ \lesssim i_{p_1-b_1} \lesssim 130^\circ$, this method does not yield a maximum eccentricity (i.e. no solutions can be found). The semi-analytic curves approximately capture the low-inclination dependence of $e_{\text{max},b_1}$ on $i_{p_1-b_1}$. The larger $i_{b_1-b_2}$, the larger $e_{\text{max},b_1}$. The dependence of $e_{\text{max},b_1}$ on $i_{p_1-b_1}$ explains why in Fig. 30, where $i_{p_1-b_1}$ varies per point, $e_{\text{max},b_1}$ is typically below the black dashed analytic curves, which assume only a perturbation by $b_1$, and no additional precession due to orbit $p_1$.

These results show that it is unlikely that orbits $p_1$ and $b_1$ are highly inclined (i.e. a mutual inclination close to $90^\circ$). If this were the case, then the planet would become highly eccentric and tidally interact with, or collide with 30 Ari B. Furthermore, more moderate inclinations of $40^\circ \lesssim i_{p_1-b_1} \lesssim 60^\circ$ and $120^\circ \lesssim i_{p_1-b_1} \lesssim 140^\circ$ are also not likely because orbit $b_1$ could be excited to high eccentricity, up to $\approx 0.8$. This would trigger a dynamical instability in the planetary orbit, possibly resulting in the ejection of the planet from the system, or a collision with one of the stars. Therefore, low inclinations are more likely, i.e. $0^\circ \lesssim i_{p_1-b_1} \lesssim 40^\circ$ or $140^\circ \lesssim i_{p_1-b_1} \lesssim 180^\circ$ (based on these results, we cannot make constraints with respect to prograde or retrograde orbits). Because of the degeneracy of $e_{\text{max},b_1}$ with respect to both $i_{p_1-b_1}$ and $i_{b_1-b_2}$, no strong constraints can be put on $i_{b_1-b_2}$.

**4.1.2 Constraints on additional planets**

As a further application, we consider one plausible realization of 30 Ari, and insert an additional planet in orbit around 30 Ari B, outside of the orbit of the observed planet 30 Ari Bb and within the orbit of 30 Ari C. Effectively, the system is then a hierarchical sextuple system. The orbit of the additional planet (‘$p_2$’) is assumed to be initially coplanar with orbit $p_1$, and its eccentricity is $e_{p_2} = 0.01$. Furthermore, we adopt a mutual inclination of $p_1$ and $p_2$ with respect to orbit $b_1$ of $i_{p_1-b_1} = i_{p_2-b_1} = 40^\circ$. The inclination between orbits $b_1$ and $b_2$ is also assumed to be $i_{b_1-b_2} = 40^\circ$. We assume $e_{b_1} = 0.01$ and $e_{b_2} = 0.21$.

As free parameters, we consider the mass $m_{p_2}$ and semimajor axis $a_{p_2}$. Using the formulae of Holman & Wiegert (1999), the lower limit on $a_{p_2}$ based on dynamical stability with respect to 30 Ari B and 30 Ari Bb (i.e. $p_1$) is $a_{p_2} \gtrsim 2.9$ au. Similar arguments with respect to 30 Ari C require $a_{p_2} \lesssim 7.6$ au (assuming $e_{p_2} = 0.01$). Based on this, we take a linear grid in $a_{p_2}$ with $3.5 \lesssim a_{p_2}/a_\text{b} \lesssim 7.5$. The masses are taken from a linear grid in $\log_{10}(m_{p_2}/M_\odot)$, with $-3 \lesssim \log_{10}(m_{p_2}/M_\odot) \lesssim 1$.

In Fig. 31, we show in the $(a_{p_2}, e_{p_2}/e_{\text{b}_2})$-plane the systems that remain stable (green points), and that become unstable (red crosses). Here, unstable systems are due to collisions or tidal interactions of $p_1$ with the star 30 Ari B ($\approx 0.06$ of the systems), or orbit crossings of the additional planet $p_2$ with the first planet ($\approx 0.60$ of the systems).
There is a noticeable dependence of stability on time; to illustrate this, we include two integration times in Fig. 31: 100 Myr (top panel) and 1 Gyr (bottom panel). As can be expected, more systems become unstable as time progresses. Regardless of age, the additional planet should be placed sufficiently far from the innermost planet. Whereas short-term dynamical stability would allow \( a_2 < a_0/M \), this is no longer the case when taking into account secular evolution. For \( t_{\text{end}} = 1 \) Gyr, the minimum semimajor axis, \( a_1 \approx 6 \), is a factor of \( \sim 2 \) larger compared to the situation when only short-term dynamical stability is taken into account (2.9 au).

Generally, there are no strong constraints on the mass of the additional planet. This can be understood by noting that the excitation of the eccentricity of \( p_2 \) by \( b_1 \) is independent of \( m_{p_2} \) as long as \( m_{p_2} \ll m_C \).

Furthermore, in Fig. 32, we show the maximum eccentricities in orbits \( p_1 \) (blue bullets), \( p_2 \) (red crosses) and \( b_1 \) (green triangles), as a function of the parameters \( a_{p_2} / \text{AU} \) and \( m_{p_2} / M_J \) (left-hand panel) and \( m_{b_1} / M_J \) (right-hand panel), with \( t_{\text{end}} = 1 \) Gyr. For sufficiently massive planets and sufficiently large semimajor axes, the additional planet can increase the maximum eccentricities of the orbit of \( p_1 \), and, to a minor extent, the orbit of \( b_1 \).

To conclude, assuming a low mutual inclination between orbits \( p_1 \) and \( b_1 \) and \( e_{p_1} = 0.01 \) and \( e_{b_1} = 0.21 \), we find a region of secular dynamical stability of an additional planet around 30 Ari B, outside of and coplanar with the orbit of 30 Ari Bb. The semimajor axis of the orbit of this additional planet should be confined to a narrow range, \( 6 \lesssim a_{p_2}/\text{au} \lesssim 7.6 \), whereas there are no strong constraints on mass of the planet (cf. the bottom panel of Fig. 31). Furthermore, the eccentricity of the orbit is likely high, possibly as high as \( \sim 0.6 \) (cf. Fig. 32).

### 4.2 Mizar and Alcor

Mizar and Alcor is perhaps one of the most well-known nearby hierarchical stellar multiple systems. To date, it is known to be a sextuple system. Mizar and Alcor form a visual stellar binary, which is famous for being used as a vision test (Allen 1899). Mizar itself is also a visual binary, known from as early as 1617, when Benedetto Castelli reported resolving it in a letter to Galileo Galilei (Ondra \( \text{et al.} \) 2004; Siebert 2005). Both components of Mizar, Mizar A and B, are spectroscopic binaries. Mizar A is the first spectroscopic binary known, found by Antonia Maury and reported by Pickering (1890); the spectroscopic binary Mizar B was discovered independently by Frost (1908) and Ludendorff (1908). Recently, Alcor was found to be a binary as well (Mamajek \( \text{et al.} \) 2010; Zimmerman \( \text{et al.} \) 2010). It has been disputed whether or not Mizar is gravitationally bound to Alcor. In the recent works of Mamajek \( \text{et al.} \) (2010) and Zimmerman \( \text{et al.} \) (2010), it was found that this is likely the case. To our knowledge, the secular dynamics of the system have not been explored.

In Fig. 33, we show the hierarchy of the system in a mobile diagram. Mizar forms a ‘2+2’ quadruple system, orbited by the binary Alcor. Based on the studies mentioned above, we assume masses \( m_i/M_\odot = \{ 2.43, 2.50, 1.6, 1.6, 1.8, 0.3 \} \), semimajor axes \( a_i/\text{au} = \{ 0.25, 0.9, 5.9 \times 10^2, 2.8 \times 10^3, 7.4 \times 10^3 \} \) and eccentricities \( e_i = \{ 0.53, 0.46, 0.3, 0.3, 0.3 \} \). For the unknown eccentricities of \( b_1 \), \( b_2 \) and \( b_3 \), we assume a value of 0.3, a typical value for long-period binaries (Raghavan \( \text{et al.} \) 2010).

Below, we evaluate the characteristic quantities \( \mathcal{R}^{(bb)} \) (cf. equation 10) for the relevant binary combinations, setting the quantities
C to unity. For the ‘outermost’ binary–binary combination (b_3, b_1, b_2), we find
\[ R_{345}^{(bb)} \sim \left( \frac{a_{b_3}}{a_{b_1}} \right)^{3/2} \left( \frac{m_1 + m_2 + m_3 + m_4}{m_5 + m_6} \right)^{3/2} \approx 8 \times 10^{-2}, \]
(23)
indicating that the binary nature of b_4 can typically be neglected. Moreover, even for the pair (b_1, b_3), the LK time-scale (cf. equation 7 with \( C = 1 \)) is \( P_{\text{LK,35}} \sim 33 \text{ Gyr} \), which is much longer than the age of the system, \( \approx 0.5 \text{ Gyr} \). Therefore, LK cycles in the outermost binaries b_1, b_3, and b_2 are not important during the lifetime of the system.

For the ‘innermost’ combination (b_1, b_2, b_3), we find
\[ R_{123}^{(bb)} \sim \left( \frac{a_{b_2}}{a_{b_3}} \right)^{3/2} \left( \frac{m_1 + m_2}{m_3 + m_4} \right)^{3/2} \approx 1 \times 10^1, \]
(24)
showing that LK cycles are typically more important in the (b_2, b_3) pair compared to the (b_1, b_2) pair. Nevertheless, resonant behaviour might be expected in some cases. Using equation (7), the individual LK time-scales are
\[ P_{\text{LK,13}} \sim 980 \text{ Myr}; \quad P_{\text{LK,23}} \sim 74 \text{ Myr}, \]
(25)
showing that during the lifetime of the system, the order of 10 eccentricity oscillations could have occurred in binary b_2.

However, the above does not take into account relativistic precession. In fact, the 1PN time-scales in both binaries b_1 and b_2 are much shorter compared to their respective LK time-scales. Using equation (A147), we find
\[ t_{1\text{PN},b_1} \approx 0.1 \text{ Myr}; \quad t_{1\text{PN},b_2} \approx 4 \text{ Myr}, \]
(26)
showing that LK cycles are likely (nearly) completely quenched.

We show an example in Fig. 34, where in the top panel, we show the eccentricities assuming only Newtonian terms, and in the bottom panel the pairwise 1PN terms are also included. Even though the initial mutual inclinations \( i_1 = 30^\circ \) and \( i_2 = 35^\circ \) are high, with the inclusion of the 1PN terms, oscillations are severely quenched. We conclude that secular evolution is not important in the Mizar and Alcor system.

5 DISCUSSION

5.1 The validity of orbit averaging

In our derivations, we orbit averaged the Hamiltonian after the expansion in ratios of separation ratios over all orbits (cf. Section 2.3). As shown recently by Luo, Katz & Dong (2016), in the case of hierarchical triple systems with moderately large octupole parameters (\( \epsilon_{\text{oct}} \gtrsim 10^{-3} \)) and large mass ratios of the tertiary body with respect to the inner binary (\( m_3/(m_1 + m_2) \gtrsim 10^3 \)), the double averaging technique can result in errors compared to the true secular evolution (for example, as measured by the fraction in an ensemble of systems in which orbital flips occur). Physically, this discrepancy arises from oscillations of the inner orbital angular momentum vector on time-scales of the outer orbital period (Antonacci & Perets 2012; Katz & Dong 2012; Antognini et al. 2014), which invalidates the assumption of a fixed inner orbit during the orbit of the tertiary. These effects very likely also apply, to some cases, to the more general hierarchical N-body systems considered in this paper. A similar technique as used by Luo et al. (2016), i.e. to apply a ‘correction’ in the process of averaging over the outer body, might also be applied to hierarchical N-body systems. However, such an analysis is beyond the scope of this work.

5.2 Short-term instabilities

The assumptions on which the \textsc{secularmultiple} algorithm is based (cf. Section 1) should be considered not only for the initial conditions of the systems, but also for the subsequent secular evolution. In particular, when eccentricities become high, there is the possibility that dynamical instabilities are triggered on short-term scales, i.e. of the order of the orbital periods. These dynamical instabilities are not taken into account in the secular equations of motion. For example, in multiplanet systems, dynamical instabilities are triggered when the Hill or Laplace boundaries are approached for sufficiently eccentric orbits.

For this reason, a number of stopping conditions are implemented in \textsc{secularmultiple} that use various stability criteria to evaluate the importance of short-term dynamical instabilities. These criteria are approximate, however. In order to investigate more accurately whether the system is short-term dynamically stable, \textsc{secularmultiple} allows for the user to easily switch to direct N-body integration. A complication of the latter is that the orbital phases are inherently not modelled in \textsc{secularmultiple} but evidently, they are required...
for direct \( N \)-body integration. In practice, it is therefore necessary to carry out an ensemble of \( N \)-body integrations with e.g. randomly sampled orbital phases.

Typically, when a dynamical instability occurs, this happens on a time-scale that is short compared to secular time-scales. The resulting configuration is likely again hierarchical. Therefore, although \textsc{secularmultiple} cannot be used to model the short-term phase of dynamical instability itself, once a new stable configuration has been attained, it can again be used to model the subsequent secular evolution. In future work, we intend to use this approach to study the secular stability of multiplanet systems, both in single- and multistar configurations.

6 CONCLUSIONS

We have presented a new method for studying the secular dynamics of hierarchical \( N \)-body systems composed of nested binaries with an arbitrary number of bodies and an arbitrary hierarchical configuration. This algorithm is suitable for studying the secular evolution of hierarchical systems with complex hierarchies, making long-term integrations of such systems feasible. We have applied the method to various multiplanet and multistar systems. Our main conclusions are as follows.

(1) We have derived the expanded and orbit-averaged Hamiltonian for the system (a complete self-contained derivation is given in Appendix A). Our main assumptions are that the system is hierarchical, i.e. the ratios \( x_i \) of the separation vectors are small, and that orbit averaging is applicable (i.e. the time-scales for angular momentum changes are much longer than orbital time-scales). The results from the expansion are summarized below.

(a) To first order in \( x_i \) (‘dipole order’), all terms vanish identically for any hierarchical configuration.

(b) To order \( x_i^2 \) (‘quadrupole order’), the Hamiltonian consists of terms which, individually, depend on binary pairs. These pairwise terms are mathematically equivalent to the quadrupole-order terms of the hierarchical three-body Hamiltonian.

(c) To order \( x_i^3 \) (‘octupole order’), the Hamiltonian consists of two types of terms: terms which, individually, depend on binary pairs, and terms which, individually, depend on binary triplets. The pairwise terms are mathematically equivalent to the term depending on three binaries at the octupole order in the hierarchical three-body Hamiltonian. The triplet terms are mathematically equivalent to the term depending on three binaries at the octupole order in the hierarchical four-body Hamiltonian (‘3+1’ configuration; this term was first derived by Hamers et al. 2015).

(d) Generally, to order \( x_i^n \), there are \( n - 1 \) types of terms (i.e. depending on binary pairs, triplets, etc.). The individual terms depend on at most \( n \) binaries. Whether all these terms appear is contingent on the system: if the system does not contain a sufficiently complex hierarchy, then not all types of terms may appear.

In summary, the general hierarchical \( N \)-body Hamiltonian can be constructed from the Hamiltonians of smaller subsystems. The higher the order of the expansion, the larger the number of binaries within these subsystems.

(2) We have explicitly derived the expanded Hamiltonian up and including octupole-order, and including the pairwise hexadecupole- and dotriacontupole-order terms (cf. Appendix A5.2). We orbit-averaged these terms, and also gave a general expression for the orbit-averaged binary pair term to order \( n \) in terms of derivatives of polynomial functions (cf. Appendix A5.3). Note that for hierarchical triple systems, the Hamiltonian consists exclusively of these pairwise terms. Also, in the case of systems with more complex hierarchies, the pairwise terms are expected to be typically dominant.

(3) We presented a new algorithm within the \textsc{amuse} framework, \textsc{secularmultiple}, to numerically solve the resulting equations of motion. The new algorithm allows for fast long-term integration of hierarchical systems, opening up the possibility for studying the long-term dynamics of complex hierarchical systems without having to resort to costly \( N \)-body integrations. Tidal friction and precession due to relativity and tidal bulges are also included in an approximate approach, treating each binary as an isolated system.

(4) As a first demonstration, we showed that \textsc{secularmultiple} can be used for the secular dynamics of multiplanet systems in both single-star and multiple-star systems. For the case of a single-star system (cf. Section 3.1), we compared our results to LL theory in the regime of low eccentricities and inclinations, in which LL theory is essentially exact (barring the effects of mean motion resonances).

We found that \textsc{secularmultiple} produces results that differ by only \( \sim 2 \) per cent with LL theory, provided that the spacing between the planets is \( K_0 \gtrsim 10 \) (equivalently, a semimajor axis ratio \( \lesssim 0.4 \)), and that sufficiently high-order pairwise binary terms, as high as the dotriacontupole-order (fifth order in \( \chi \)), are included. In the systems that we considered, the octupole-order binary triplet terms do not affect the secular dynamics. More generally, for any order \( n \), we estimated that the non-pairwise binary terms are not important for nested systems with a central massive body, and with the other bodies of comparable mass.

(5) Whereas LL theory only applies to planetary systems with low eccentricities and inclinations and with a central massive object, our method can also be used in the case of arbitrary eccentricities (provided that the \( x_i \) remain sufficiently small), inclinations and hierarchies. In particular, we showed that \textsc{secularmultiple} can be used to efficiently study multiplanet systems in binary- and triple-star systems (cf. Sections 3.2 and 3.3, respectively). In the case of triple-star systems in which the tertiary star has multiple S-type planets, we showed that, compared to the case of a binary-star system, the ‘binary nature’ of the companion in the case of a stellar triple can result in both dynamical protection and destabilization of the planets against the stellar torques, depending on the configuration.

(6) We applied our method to the observed stellar quadruple system 30 Arietis (30 Ari), which harbour a massive planet, 30 Ari Bb. The mutual inclinations in this system are unknown. Using secular stability arguments, we showed that the orbit of the planet is likely not highly inclined with respect to 30 Ari C. Furthermore, assuming the latter, we found that there is a narrow region in semimajor axis space \( 6 \lesssim a_p/\text{au} \lesssim 7.6 \) which allows for the presence of an additional planet beyond the orbit of 30 Ari Bb and inside of the orbit of 30 Ari C. The eccentricity of the orbit of the additional planet would likely be high, possibly as high as \( \sim 0.6 \).

We will make \textsc{secularmultiple} publicly available within AMUSE\footnote{amusecode.org} by 2016.

ACKNOWLEDGEMENTS

We thank the referee, Will Farr, for providing very useful comments, and for motivating us to further generalize our results. This work was supported by the Netherlands Research Council NWO (grants #639.073.803 [VICI], #614.061.608 [AMUSE] and
APPENDIX A: DERIVATION OF THE EXPANDED AND ORBIT-AVERAGED HIERARCHICAL MULTIPLE HAMILTONIAN

In this appendix, we derive the Hamiltonian $H$ for a hierarchical multiple system consisting of nested binaries with an arbitrary number of bodies and hierarchy, expanded in ratios of the binary separations (cf. Appendices A1, A2, A3 and A4). Subsequently, we orbit average the Hamiltonian (cf. Appendix A5). Lastly, we give an ad hoc expression for the 1PN Hamiltonian (cf. Appendix A7).

A1 Description of the system structure

Consider a system of $N$ point masses $m_i \in \{m_1, \ldots, m_N\}$ with position vectors $\mathbf{R}_i \in \{\mathbf{R}_1, \ldots, \mathbf{R}_N\}$, arranged in $N - 1$ binary orbits (see Fig. 1 for an example quintuple system). The relative position vectors between binaries and/or bodies are denoted by $\mathbf{r}_i$, where generally $i \leq N - 1$; let $B = \{i; i \leq N - 1\}$ denote the corresponding set of indices. The hierarchy of the system is specified using the mass ratio matrix $A$ according to

$$ \mathbf{r}_i = \sum_{k=1}^{N} A_{ik} \mathbf{R}_k. \quad (A1) $$

By definition, the last row in $A$, i.e. $A_{N1}$, corresponds to the centre of mass $\mathbf{r}_N$, and is given by $A_{N1} = m_N / M$, where

$$ M = \sum_{i=1}^{N} m_i, \quad (A2) $$

is the total mass of the system. For convenience in a number of examples below, we also introduce the following notation for the partial sum over the masses,

$$ M_{n,i} \equiv \sum_{a=i}^{j} m_a. \quad (A3) $$

For example, a hierarchical triple system (the simplest hierarchical multiple system) is represented by

$$ A = \begin{pmatrix} 1 & -1 & 0 \\ \frac{m_1}{M_{12}} & \frac{m_2}{M_{12}} & \frac{m_1}{M} \\ \frac{m_1}{M_{13}} & \frac{m_2}{M_{13}} & \frac{m_1}{M} \end{pmatrix}, \quad (A4) $$

which implies $r_1 = R_1 - R_2$ and $r_2 = \left( m_1 R_1 + m_2 R_2 \right) / (m_1 + m_2) - R_1$. With this definition of $A$, $r_1$ corresponds to the relative separation vector of the inner binary between $R_1$ and $R_2$, whereas $r_2$ corresponds to the relative separation vector in the outer binary between the centre of mass of the inner binary and $R_3$. Another example, which is also used for further illustration below, is a hierarchical quintuple consisting of a triple–binary pair,

$$ A = \begin{pmatrix} 1 & -1 & 0 & 0 & 0 \\ \frac{m_1}{M_{12}} & \frac{m_2}{M_{12}} & -1 & 0 & 0 \\ \frac{m_1}{M_{13}} & \frac{m_2}{M_{13}} & \frac{m_1}{M} & 1 & -1 \\ \frac{m_1}{M_{14}} & \frac{m_2}{M_{14}} & \frac{m_1}{M} & \frac{m_1}{M} & \frac{m_1}{M} \end{pmatrix}. \quad (A5) $$

A schematic representation of this system in a mobile diagram is given in Fig. 1. Note that the order of the rows in $A$ sets the labels on the binary separation vectors $r_i$, and the signs determine the directions of the $r_i$.

The inverse relation between (absolute) position vectors and relative binary separation vectors is given by the inverse matrix of $A$, i.e.

$$ \mathbf{R}_i = \sum_{k=1}^{N} A_{ik}^{-1} \mathbf{r}_k. \quad (A6) $$

The potential energy (cf. Appendix A2) is expressed in terms of distances between pairs of bodies, $||\mathbf{R}_i - \mathbf{R}_j||$. Using equation (A6), the difference vectors can be written as

$$ \mathbf{R}_i - \mathbf{R}_j = \sum_{k=1}^{N} \left( A_{ik}^{-1} - A_{jk}^{-1} \right) \mathbf{r}_k \equiv \sum_{k=1}^{N} B_{ijk} \mathbf{r}_k, \quad (A7) $$

where we defined the quantity

$$ B_{ijk} \equiv A_{ik}^{-1} - A_{jk}^{-1}. \quad (A8) $$

Another quantity derived from $A$, used for the kinetic energy (cf. Appendix A3), is

$$ C_{ik} \equiv A_{ik}^{-1} A_{ik}^{-1}. \quad (A9) $$

Before proceeding with the expansion of the potential energy in Appendix A2, we first introduce a number of useful definitions, and discuss some general properties of the three-index quantities $B_{ijk}$ (Appendix A1.1) and $C_{ik}$ (Appendix A1.2).
Table A1. The values of $B_{ik}$ (cf. equation A8) for the quintuple system depicted in Fig. 1. Columns correspond to pairs of bodies $(i, j)$; rows correspond to binaries $k$. The partial mass sums $M_{l,j}$ are defined in equation (A3). Note that $B_{ik} = -B_{jk}$ and $B_{ik} = 0$ (cf. equation A8).

Children, siblings and descendants. We refer to the two members of a binary $k$ as the ‘children’ of that binary, i.e. child 1 and child 2, denoted by ‘$k.C1$’ and ‘$k.C2$’. The children can be either bodies or binaries themselves. Each child has a sibling, i.e. the binary or body with the same parent binary. For a binary pair ($k$, l), where $l$ is a direct or indirect child of $k$, we use ‘$k.CS(l)$’ to denote the sibling in $k$ of the child in $k$ that is connected to $l$.

We define a descendant of a binary $k$ as a body or binary that is connected to $k$ via one of the children of $k$, not necessarily directly. For example, in Fig. 1, bodies 1 and 2 are descendants of binary 4, whereas they are not descendants of binary 3. The set of all descendant bodies of a binary $k$ is denoted with ‘$\{k.C\}$’, and the body descendant sets within the children of $k$ are denoted with ‘$\{k.Cn\}$’ for child $n$. These notations will be used frequently below.

Masses. The mass of binary $k$, $M_k$, is defined as the sum of the masses of all bodies contained within the hierarchy of binary $k$. The masses of the children of binary $k$ are denoted with $M_{k.C1}$ and $M_{k.C2}$, which, evidently, satisfy

$$M_{k,C1} + M_{k,C2} = M_k.$$  \hspace{1cm} (A10)

Furthermore,

$$\sum_{i \in \{k.Cn\}} m_i = M_{Cn}. \hspace{1cm} (A11)$$

Levels. We define the ‘level’ of a binary $k$ as the number of binaries that needs to be traversed to reach $k$, starting from the ‘absolute top’ binary of the system, i.e. the binary for which all other binaries are children. For example, in Fig. 1, the top binary is binary 4 with level 0. We denote the level of binary $k$ with ‘$k.L$’.

The ‘sign quantity’ $\alpha(i, j; k)$. For any pair of bodies or binaries $(i, j)$, there is a unique path, i.e. a set of binaries, connecting $i$ and $j$. Let this path be denoted by $B_p = B_p(i, j)$. For a given path $B_p$ and a given binary $k$, we define the quantity $\alpha = \alpha(i, j; k)$ for which

$$\alpha(i, j; k) = \pm 1. \hspace{1cm} (A12)$$

The positive (negative) sign applies when in binary $k$, the path $B_p$ is opposed to (directed along) the direction of $r_k$. In other words, if $r_k$ is defined such that it points from ‘child 2’ to ‘child 1’ in binary $k$, then the sign is positive if the path in $B_p$ leads from child 2 to child 1 (directed against $r_k$), and negative if path in $B_p$ leads from child 2 to child 1 (directed along $r_k$). From this, it also immediately follows that $\alpha(i, j; k) = -\alpha(i, j; k)$. Also, for $j \notin \{k.C1\}$ and $j \notin \{k.C2\}$, $\alpha(k.C1, j; k) = -\alpha(k.C2, j; k)$.

For example, in Fig. 1, $\alpha(1, 2; 1) = 1$, $\alpha(2, 1; 1) = -1$, $\alpha(1, 5; 4) = 1$, and $\alpha(5, 1; 4) = -1$.

A1.1 General properties of $B_{ik}$

By definition (cf. equation A7), the first two indices in $B_{ik}$ refer to bodies, whereas the third index refers to a binary. Given pair $(i, j)$ with path $B_p = B_p(i, j)$ and given binary $k$, the following properties of $B_{ik}$ apply.

(i) $B_{ik} = -B_{jk}$ (this follows immediately from equation A8).

(ii) $B_{ik} = 0$ if $k \notin B_p(i, j)$ or $k = N$ (in the latter case, $k$ corresponds to the centre of mass).

(iii) $B_{ik} = \alpha(i, j; m)$ if binary $k \in B_p$ and both children of $k$ are part of $B_p$. In other words, $k$ is the lowest level, or ‘top’ binary in $B_p$. Below, we refer to this binary with the ‘special’ index $m = m(i, j)$. There is a unique binary $m$ for every path $B_p$ between bodies $i$ and $j$. For example, in Fig. 1, for $B_p(i, j) = B_p(1, 4)$, the top binary is $m(1, 4) = 4$.

(iv) Otherwise, $B_{ik} = \alpha(i, j; k) M_{k.C3-n}/M_i$ if $i$ and $j$ are connected to each other through child $n$ of $k$ (here, $n$ is either 1 or 2).

To illustrate these properties, we give in Table A1 the values of $B_{ik}$ for our example quintuple system depicted in Fig. 1, computed directly from the definition equation (A8).
Table A2. The values of $C_{kl}$ (cf. equation A9) for the quintuple system depicted in Fig. 1. Columns correspond to pairs of binaries $(k, l)$; rows correspond to bodies $i$. The partial mass sums $M_{ik}$ are defined in equation (A3). Note that $C_{kl} = C_{lk}$ (cf. equation A9).

(A1.2) General properties of $C_{kl}$

In $C_{kl}$, the first index refers to a body, whereas the second and third indices refer to binaries. From the definition in equation (A9), it immediately follows that $C_{kl} = C_{lk}$. For a pair of binaries $(k, l)$, let $p$ denote the binary with the highest level, and $q$ the binary with the lowest level (i.e. binary $p$ is ‘below’ $q$). The following properties apply:

(i) $C_{kl} = 0$ if $k \neq l$ and binaries $k$ and $l$ have the same level.

(ii) $C_{kl} = 0$ if $i$ is not a descendant of both binaries $k$ and $l$.

(iii) $C_{kl} = M_{i1}^{(3-n)} M_{j1}^{(3-n)}$ if $k = l$ and $i$ is connected to $k$ through child $n$ of $k$.

(iv) $C_{kl} = \alpha(i, q; p) \alpha(i, q; q) M_{p(C\alpha - 3)} M_{q(C\alpha(p)}/(M_{p} M_{q})$ if $i$ is a descendant of $p$, and $i$ is connected to $p$ through child $n$ of $p$. The product of two sign quantities implies that $C_{kl}$ is positive if the path from body $i$ to binary $q$ is either opposed to or directed along both directions of $r_p$ and $r_q$. The sign of $C_{kl}$ is negative if the path in from body $i$ to binary $q$ is opposed to the direction of $r_p$ and directed along $r_q$, or if the path in from body $i$ to binary $q$ is directed along the direction of $r_p$ and opposed to $r_q$.

The values of $C_{kl}$ for our example quintuple system depicted in Fig. 1, computed from equation (A9), are given for illustration in Table A2.

(A2) Expansion of the potential energy

The Newtonian potential energy $V$ is given by

$$V = -G \sum_{i \neq j} \frac{m_i m_j}{|\mathbf{R}_i - \mathbf{R}_j|}. \quad (A13)$$

Our approach is to write $V$ in terms of the $r_i$, and to expand it in terms of the (assumed to be) small separation ratios $x_i$ (defined more precisely below).

Using equation (A7), the norm of the separation vector between two pairs of bodies can be written as

$$||\mathbf{R}_i - \mathbf{R}_j|| = \left(\left|\mathbf{R}_i - \mathbf{R}_j\right| \cdot \left(\mathbf{R}_i - \mathbf{R}_j\right)\right)^{1/2} = \left[\sum_{i=1}^{N} \sum_{j=1}^{N} B_{ijk} B_{ijl} (r_k \cdot r_l)\right]^{1/2} = \left[\sum_{k \in \mathbb{B}} \sum_{l \in \mathbb{B}} B_{ijk} B_{ijl} (r_k \cdot r_l)\right]^{1/2} \quad (A14)$$

Here, we defined $\mathbb{B} \equiv \mathbb{B} \setminus \{m\}$ as the set of binaries excluding binary $m$, where $m = m(i, j)$ is the lowest level, or ‘top’ binary in $B_q(i, j)$, the path of binaries between bodies $i$ and $j$. Evidently, $\hat{\mathbf{r}}_m \cdot \hat{\mathbf{r}}_m = 1$, and as mentioned in Appendix A1.1, $B_{ijm} = \alpha(i, j; m)$, hence $B_{ijm}^2 = (\pm 1)^2 = 1$.

By our assumption of hierarchy, $r_m$ is the largest of the separations $r_k$ in the path $B_q(i, j)$, i.e. if $k \in B_q(i, j)$, then $r_k \ll r_m$ if $k \neq m$. Furthermore, $B_{ijk}$ and $\alpha(i, j; m)$ always satisfy $|B_{ijk}| \leq 1$ and $|\alpha(i, j; m)| = 1$. Therefore, for (sufficiently) hierarchical systems, it is appropriate to expand the potential in terms of $x_i = r_k / r_m \ll 1$. The less hierarchical the system, the more terms of higher orders need to be included.

The expression for $||\mathbf{R}_i - \mathbf{R}_j||^{-1}$ is a function of a set of small (compared to zero) variables $\{x_i\}$, where $n \in \mathbb{B}$. The multivariate function that needs to be expanded is

$$f(x_n) = \left[\sum_{k \in \mathbb{B}} \sum_{l \in \mathbb{B}} B_{ijk} B_{ijl} (\hat{r}_k \cdot \hat{r}_l) x_k x_l + 2 \alpha(i, j; m) \sum_{k \in \mathbb{B}} B_{ijk} (\hat{r}_k \cdot \hat{r}_m) x_k + 1 \right]^{1/2}. \quad (A15)$$

To \( \mathcal{O}(x^5) \), the general Taylor expansion of \( f\{x_n\} \) for all \( x_n \) near 0 reads

\[
\begin{align*}
 f\{x_n\} = f\{x_n = 0\} + \sum_{p \in \mathbb{P}} \frac{\partial f}{\partial x_p} \bigg|_{x_n = 0} x_p + \frac{1}{2} \sum_{p \in \mathbb{P}} \sum_{q \in \mathbb{P}} \sum_{u \in \mathbb{P}} \frac{\partial^2 f}{\partial x_p \partial x_q \partial x_u} \bigg|_{x_n = 0} x_p x_q x_u \\
+ \frac{1}{2 \cdot 3 \cdot 4} \sum_{p \in \mathbb{P}} \sum_{q \in \mathbb{P}} \sum_{u \in \mathbb{P}} \sum_{v \in \mathbb{P}} \frac{\partial^3 f}{\partial x_p \partial x_q \partial x_u \partial x_v} \bigg|_{x_n = 0} x_p x_q x_u x_v \\
+ \frac{1}{2 \cdot 3 \cdot 4 \cdot 5} \sum_{p \in \mathbb{P}} \sum_{q \in \mathbb{P}} \sum_{u \in \mathbb{P}} \sum_{v \in \mathbb{P}} \sum_{w \in \mathbb{P}} \frac{\partial^4 f}{\partial x_p \partial x_q \partial x_u \partial x_v \partial x_w} \bigg|_{x_n = 0} x_p x_q x_u x_v x_w + \mathcal{O}(x^6).
\end{align*}
\]

(A16)

Computing the required partial derivatives of \( f \), we find

\[
\frac{1}{\| \mathbf{R}_i - \mathbf{R}_j \|} = \frac{1}{r_m} \left\{ S_0 + S_1 + S_2 + S_3 + S_4 + S_5 + \mathcal{O}(x^6) \right\},
\]

(A17)

where \( S_0 \) denote terms of order \( x^0 \). Up and including fifth order, they are given by

\[
S_0 = 1;
\]

(A18)

\[
S_1 = -\alpha(i, j; m) \sum_{p \in \mathbb{P}} B_{ij} \beta_1(p, r_m);
\]

(A19)

\[
S_2 = \frac{1}{2} \sum_{p \in \mathbb{P}} \sum_{q \in \mathbb{P}} B_{ij} B_{jq} \beta_2(p, q, r_m);
\]

(A20)

\[
S_3 = -\frac{1}{2} \alpha(i, j; m) \sum_{p \in \mathbb{P}} \sum_{q \in \mathbb{P}} \sum_{u \in \mathbb{P}} B_{ij} B_{jq} B_{ju} \beta_2(p, q, r, u, r_m);
\]

(A21)

\[
S_4 = \frac{1}{8} \sum_{p \in \mathbb{P}} \sum_{q \in \mathbb{P}} \sum_{u \in \mathbb{P}} \sum_{v \in \mathbb{P}} B_{ij} B_{jq} B_{ju} B_{uv} \beta_3(p, q, r, u, v, r_m);
\]

(A22)

\[
S_5 = -\frac{1}{8} \alpha(i, j; m) \sum_{p \in \mathbb{P}} \sum_{q \in \mathbb{P}} \sum_{u \in \mathbb{P}} \sum_{v \in \mathbb{P}} \sum_{w \in \mathbb{P}} B_{ij} B_{jq} B_{ju} B_{uv} B_{w} \beta_3(p, q, r, u, v, w, r_m).
\]

(A23)

Here, the functions \( \beta_n \) are given by

\[
\beta_1(p, r_m) \equiv \frac{r_p}{r_m} (\hat{r}_p \cdot \hat{r}_m);
\]

(A24)

\[
\beta_2(r_p, r_q, r_m) \equiv \frac{r_p}{r_m} \frac{r_q}{r_m} \left[ 3(\hat{r}_p \cdot \hat{r}_m)(\hat{r}_q \cdot \hat{r}_m) - (\hat{r}_p \cdot \hat{r}_q) \right];
\]

(A25)

\[
\beta_3(r_p, r_q, r_u, r_m) \equiv \frac{r_p}{r_m} \frac{r_q}{r_m} \frac{r_u}{r_m} \left[ 5(\hat{r}_p \cdot \hat{r}_m)(\hat{r}_q \cdot \hat{r}_m)(\hat{r}_u \cdot \hat{r}_m)(\hat{r}_u \cdot \hat{r}_m) - (\hat{r}_p \cdot \hat{r}_m)(\hat{r}_q \cdot \hat{r}_u)(\hat{r}_u \cdot \hat{r}_m) - (\hat{r}_p \cdot \hat{r}_u)(\hat{r}_q \cdot \hat{r}_m)(\hat{r}_u \cdot \hat{r}_m) - (\hat{r}_p \cdot \hat{r}_u)(\hat{r}_q \cdot \hat{r}_u)(\hat{r}_u \cdot \hat{r}_m) \right];
\]

(A26)

\[
\beta_4(r_p, r_q, r_u, r_v, r_m) \equiv \frac{r_p}{r_m} \frac{r_q}{r_m} \frac{r_u}{r_m} \frac{r_v}{r_m} \left[ 35(\hat{r}_p \cdot \hat{r}_m)(\hat{r}_q \cdot \hat{r}_m)(\hat{r}_u \cdot \hat{r}_m)(\hat{r}_v \cdot \hat{r}_m) - 5(\hat{r}_p \cdot \hat{r}_m)(\hat{r}_q \cdot \hat{r}_m)(\hat{r}_u \cdot \hat{r}_u)(\hat{r}_v \cdot \hat{r}_u) - 5(\hat{r}_q \cdot \hat{r}_m)(\hat{r}_u \cdot \hat{r}_u)(\hat{r}_v \cdot \hat{r}_u)(\hat{r}_v \cdot \hat{r}_u) - 5(\hat{r}_u \cdot \hat{r}_u)(\hat{r}_v \cdot \hat{r}_u)(\hat{r}_v \cdot \hat{r}_u)(\hat{r}_v \cdot \hat{r}_u) \right];
\]

(A27)
\[ + (\hat{\rho}_u \cdot \hat{\rho}_m)(\hat{\rho}_p \cdot \hat{\rho}_q)(\hat{\rho}_a \cdot \hat{\rho}_m) + (\hat{\rho}_u \cdot \hat{\rho}_m)(\hat{\rho}_p \cdot \hat{\rho}_q)(\hat{\rho}_a \cdot \hat{\rho}_m) + (\hat{\rho}_u \cdot \hat{\rho}_m)(\hat{\rho}_p \cdot \hat{\rho}_q)(\hat{\rho}_a \cdot \hat{\rho}_m) \]

\[ + (\hat{\rho}_u \cdot \hat{\rho}_m)(\hat{\rho}_p \cdot \hat{\rho}_q)(\hat{\rho}_a \cdot \hat{\rho}_m) + (\hat{\rho}_u \cdot \hat{\rho}_m)(\hat{\rho}_p \cdot \hat{\rho}_q)(\hat{\rho}_a \cdot \hat{\rho}_m) \]

\[ + (\hat{\rho}_q \cdot \hat{\rho}_m)(\hat{\rho}_p \cdot \hat{\rho}_q)(\hat{\rho}_a \cdot \hat{\rho}_m) + (\hat{\rho}_q \cdot \hat{\rho}_m)(\hat{\rho}_p \cdot \hat{\rho}_q)(\hat{\rho}_a \cdot \hat{\rho}_m) \]

\[ + (\hat{\rho}_p \cdot \hat{\rho}_m)(\hat{\rho}_q \cdot \hat{\rho}_a)(\hat{\rho}_a \cdot \hat{\rho}_m) + (\hat{\rho}_p \cdot \hat{\rho}_m)(\hat{\rho}_q \cdot \hat{\rho}_a)(\hat{\rho}_a \cdot \hat{\rho}_m) \].

(A28)

Generally, we formally write for order \( n \),

\[ S_n = (-1)^n \alpha(i, j; m) a \sum_{p_1, \ldots, p_n \in B} B_{ijp_1} \ldots B_{ijp_n} c_n \beta_n(r_{p_1}, \ldots, r_{p_n}, r_m), \]

(A29)

where \( c_n \) are constants. For pairwise terms, i.e. \( p_1 = \cdots = p_n = p \), we formally write \( c_n \beta_n \) as

\[ c_n \beta_n(r_{p_1}, \ldots, r_{p_n}, r_m) = c_n \beta_n(r_{p}, \ldots, r_{p}, r_m) = \sum_{j=0}^{n} \sum_{m} (r_{p} \cdot r_{m})^{j} A^{(n)}_{m} r_{m}^{-j} \]

where \( A^{(n)}_{m} \) are integer ratio coefficients. They are the same as the coefficients appearing in the Legendre polynomials. The latter can be obtained by e.g. Rodrigues’s formula, i.e.

\[ \sum_{j=0}^{n} A^{(n)}_{j} x^j = \frac{1}{2^n n!} \frac{d^n}{dx^n}[(x^2 - 1)^n]. \]

(A30)

Note that the terms \( S_n \) in which \( \hat{\rho}_m \) appears an odd number of times (i.e. if \( n \) is odd) contain the factor \( \alpha(i, j; m) \). This is to be expected: when changing the definition of \( \hat{\rho}_m \) such that it now points in the opposite direction, i.e. \( \hat{\rho}_m = -\hat{\rho}_m \), \( \alpha \) also changes sign: \( \alpha(i, j; m)^{\prime} = -\alpha(i, j; m) \). If \( \hat{\rho}_m \) appears an odd number of times, the resulting even number of minus signs cancel such that the expression in terms of \( \hat{\rho}_m \) is unaltered. The same property applies to the other separation vectors (\( \hat{\rho}_p \), \( \hat{\rho}_q \), etc.), which always appear only one time in each individual term (e.g. the term \( \hat{\rho}_p \cdot \hat{\rho}_q \) never appears). When reversing the direction of these vectors, the resulting minus sign is absorbed by the mass ratio quantities \( B_{ijp}, B_{ijq}, \) etc., which each contain a factor or that also changes sign (\( \alpha(i, j, p), \alpha(i, j, q), \) etc.). Physically, this means that the expansion of \( ||\vec{R}_i - \vec{R}_j||^{-1} \) does not depend on the choice of direction of the relative vectors, as it should be.

### A3 Derivation of the kinetic energy term

The Newtonian kinetic energy of the system is given by

\[ T = \frac{1}{2} \sum_{i=1}^{N} m_i \left( \dot{\vec{R}}_i \cdot \dot{\vec{R}}_i \right), \]

(A32)

where the dots denote derivatives with respect to time. Using equation (A6) and assuming constant masses, this can be written in terms of time derivatives of the binary separation vectors as

\[ T = \frac{1}{2} \sum_{k=1}^{N} \sum_{l=1}^{N} \sum_{i=1}^{N} m_i A_{ik}^{-1} A_{il}^{-1} (\dot{\vec{r}}_k \cdot \dot{\vec{r}}_l) = \frac{1}{2} \sum_{k=1}^{N} \sum_{l=1}^{N} \sum_{i=1}^{N} m_i A_{ik}^{-1} A_{il}^{-1} (\dot{\vec{r}}_k \cdot \dot{\vec{r}}_l) \]

\[ = \frac{1}{2} \sum_{k=1}^{N} \sum_{i=1}^{N} \sum_{k \in B} m_i C_{ik} (\dot{\vec{r}}_k \cdot \dot{\vec{r}}_i), \]

(A33)

where we used that the centre of mass, \( r_N \), satisfies \( \dot{r}_N = 0 \), and where we defined \( C_{ik} = A_{ik}^{-1} A_{il}^{-1} \) (cf. equation A9). Equation (A33) can be simplified, as shown below.

The order of the summation over \( i \) and \( k \) and \( l \) can be reversed because \( B \) and \( i \) are independent (in contrast to \( B \) and \( i \)), i.e.

\[ T = \frac{1}{2} \sum_{k \in B} \sum_{l \in B} (\dot{\vec{r}}_k \cdot \dot{\vec{r}}_l) \sum_{i=1}^{N} m_i C_{ik}. \]

(A34)

We split the double summations over binaries into several double summations over binaries, making a distinction between the relative binary levels, and into a single summation corresponding to \( k = l \) in equation (A34),

\[ T = \frac{1}{2} \sum_{p \in B} (\dot{\vec{r}}_p \cdot \dot{\vec{r}}_q) \sum_{i=1}^{N} m_i C_{ipq} + \frac{1}{2} \sum_{p \in B} \sum_{q \neq p} (\dot{\vec{r}}_p \cdot \dot{\vec{r}}_q) \sum_{i=1}^{N} m_i C_{ipq} + \frac{1}{2} \sum_{p \in B} (\dot{\vec{r}}_p \cdot \dot{\vec{r}}_q) \sum_{i=1}^{N} m_i C_{ipq} + \frac{1}{2} \sum_{p \in B} (\dot{\vec{r}}_p \cdot \dot{\vec{r}}_p) \sum_{i=1}^{N} m_i C_{ppq} . \]

(A35)

When \( p \neq q \) and the binary levels are the same (\( p.L = q.L \)), then \( C_{ipq} = 0 \) (cf. Appendix A1.2). Also, \( C_{ipq} = 0 \) if \( i \) is not a descendant of the highest level binary in \( \{ p, q \} \). Therefore, the summation over bodies \( i \) from \( i = 1 \) to \( N \) can be rewritten in terms of a summation over bodies
only in the highest level binary, i.e.

\[ T = \frac{1}{2} \sum_{p \in B} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_q) \left( \sum_{i \in \{p, C1\}} + \sum_{i \in \{p, C2\}} \right) m_i C_{ipq} + \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_q) \left( \sum_{i \in \{q, C1\}} + \sum_{i \in \{q, C2\}} \right) m_i C_{iqq} \]

\[ + \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_p) \left( \sum_{i \in \{p, C1\}} + \sum_{i \in \{p, C2\}} \right) m_i C_{ipp}. \]  

(A36)

We recall that \{ p.Cn \} denotes the set of all descendant bodies of child n of binary p. Substituting the explicit expressions for \( C_{ipq} \) and \( C_{ipp} \) (cf. Appendix A1.2), we find

\[ T = \frac{1}{2} \sum_{p \in B} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_q) \left( \sum_{i \in \{p, C1\}} m_i \alpha(p, C1, q; p) \alpha(p, C1, q; q) M_{p,C2} M_{q,C(S,p)} + \sum_{i \in \{p, C2\}} m_i \alpha(p, C2, q; p) \alpha(p, C2, q; q) M_{p,C1} M_{q,C(S,p)} \right) \]

\[ + \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_q) \left( \sum_{i \in \{q, C1\}} m_i \frac{\alpha(q, C1, p; q) \alpha(q, C1, p; p) M_{q,C2} M_{p,C(S,q)}}{M_p M_q} + \sum_{i \in \{q, C2\}} m_i \frac{\alpha(q, C2, p; q) \alpha(q, C2, p; p) M_{q,C1} M_{p,C(S,q)}}{M_p M_q} \right) \]

\[ + \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_p) \left( \sum_{i \in \{p, C1\}} m_i \frac{M_p^2 C_{21}}{M_p^2} + \sum_{i \in \{p, C2\}} m_i \frac{M_p^2 C_{21}}{M_p^2} \right) \]

\[ = \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_q) \left( M_{p,C1} \frac{\alpha(p, C1, q; p) \alpha(p, C1, q; q) M_{p,C2} M_{q,C(S,p)}}{M_p M_q} + M_{p,C2} \frac{-\alpha(p, C1, q; p) \alpha(p, C1, q; q) M_{p,C1} M_{q,C(S,p)}}{M_p M_q} \right) \]

\[ + \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_q) \left( M_{q,C1} \frac{\alpha(q, C1, p; q) \alpha(q, C1, p; p) M_{q,C2} M_{p,C(S,q)}}{M_p M_q} + M_{q,C2} \frac{-\alpha(q, C1, p; q) \alpha(q, C1, p; p) M_{q,C1} M_{p,C(S,q)}}{M_p M_q} \right) \]

\[ + \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_p) \left( \frac{M_{p,C1} M_{p,C2}}{M_p} + \frac{M_{p,C2} M_{p,C1}}{M_p} \right) \]

\[ = \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} \frac{M_{p,C1} M_{p,C2}}{M_p} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_p). \]  

(A37)

Here, we used that \( \alpha(p, C1, q; q) = \alpha(p, C2, q; q) \) and \( \alpha(p, C1, q; p) = -\alpha(p, C2, q; p) \) in the summation with \( p.L > q.L \). Similarly, in the summation with \( p.L < q.L \), \( \alpha(q, C1, p; p) = \alpha(q, C2, p; p) \) and \( \alpha(q, C1, p; q) = -\alpha(q, C2, p; q) \). The expression in equation (A37) shows that the total kinetic energy is just the sum of the kinetic energies of all the individual binaries; all terms depending on velocities of pairs of binaries cancel.

**A4 Rewriting summations in the Hamiltonian**

The Hamiltonian \( H \) is given by the sum of the kinetic and potential energies, \( H = T + V \). Equations (A13), (A17) and (A37) give the following expression for the Hamiltonian accurate to fifth order in ratios of the binary separations,

\[ H = \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} \frac{M_{p,C1} M_{p,C2}}{M_p} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_p) - \sum_{i < j} \frac{G m_i m_j}{r_{m(i,j)}} \left\{ S_{i} + S_{j} + S_{i} + S_{j} + S_{i} + S_{j} + O(x^6) \right\} \]

\[ = \frac{1}{2} \sum_{\substack{p \in B \\forall \, q \in L \, > \, p \, L}} \frac{M_{p,C1} M_{p,C2}}{M_p} (\dot{\mathbf{r}}_p \cdot \dot{\mathbf{r}}_p) + S'_0 + S'_1 + S'_2 + S'_3 + S'_4 + S'_5 + O(x^6), \]  

(A38)

where the primed quantities \( S'_n \) are defined as

\[ S'_n = -\sum_{i < j} \frac{G m_i m_j}{r_m} S_n. \]  

(A39)
Figure A1. A mobile diagram with a particular path $B_p(i,j)$, and a ‘top’ level binary $q$ (cf. Appendix A4.2). For each binary, we indicate whether or not $B_{ijp}$ is zero.

The terms $S'_0$ in equation (A38) can be simplified substantially. A key ingredient in the simplifications is to sum over binaries and their children, rather than explicitly over all pairs of bodies in the first summation of equation (A38), and to apply the properties of the mass ratio quantities $B_{ijq}$. Below we carry out these simplifications order by order.

### A4.1 Monopole-order term

The ‘monopole-order’ term $S'_0$ can be simplified by summing over all binaries and, subsequently, the children within those binaries, rather than summing explicitly over all pairs of bodies, i.e.

$$
\sum_{i<j} \sum_{r_m} \sum_{p \in B} \frac{G_m m_j}{r_m} = \sum_{i<j} \sum_{r_m} \sum_{p \in B} \frac{G_m m_j}{r_m}.
$$

(A40)

The last step in equation (A40) follows from the constancy of the separation $r_m$ for fixed $p$ and varying $i$ and $j$, and which is given by $r_p$. Therefore,

$$
-S'_0 = \sum_{i<j} \frac{G_m m_j}{r_m} = \sum_{p \in B} \sum_{i \in p} m_i \sum_{j \in p} m_j = \sum_{p \in B} \sum_{i \in p} m_i \frac{G_{p,C2}}{r_p}.
$$

(A41)

### A4.2 Dipole-order term

Here, we show that the ‘dipole-order’ term $S'_1$ (cf. equation A19) vanishes identically for any system. Using equation (A40) to rewrite the summations of pairs of bodies, $S'_1$ reads

$$
S'_1 = \sum_{i<j} \frac{G_m m_j}{r_m} \alpha(i, j; m) \sum_{p \in B} B_{ijp} \beta_1_1(r_p, r_m) = \sum_{p \in B} \sum_{i \in p} \sum_{q \in p} \frac{G_m m_j}{r_q} \alpha(i, j; q) \sum_{p \in B} B_{ijq} \beta_1_1(r_p, r_q)
$$

$$
= \sum_{p \in B} \sum_{i \in p} \sum_{q \in p} \frac{G_m m_j}{r_q} \alpha(i, j; q) \beta_1_1(r_p, r_q),
$$

(A42)

where in the last step we used that $m_i$, $m_j$, and $r_q$ are independent of $p$. We recall that $B \equiv B \setminus \{m\} = B \setminus \{q\}$ depends on $i$ and $j$. Therefore, $p$ runs over all binaries except $q$. Whenever $p$ is not part of the descendants of $q$, it is also not within the path $B_p(i,j)$ because $i$ and $j$ run over the children of $q$. Therefore, $B_{ijp} = 0$ in that case (cf. Appendix A1.1, see also Fig. A1). From this it follows that the summation of $p$ over $B$ can be rewritten as a summation of $p$ over all binaries $B$, where $p$ is a descendant of $q$, i.e.

$$
S'_1 = \sum_{q \in B} \sum_{i \in q} \sum_{j \in q} \sum_{p \in p} B_{ijq} \frac{G_m m_j}{r_q} \alpha(i, j; q) \beta_1_1(r_p, r_q).
$$

(A43)
The summation over \( p \) is now independent of \( i \) and \( j \), and can therefore be placed before the summations over \( i \) and \( j \). Also placing other quantities independent of \( i \) and \( j \) before the summations over \( i \) and \( j \), we find

\[
S'_i = \sum_{q \in B} \sum_{p \in B} G r_q \beta_i(r_p, r_q) \sum_{i \in \{q.C1\}} \sum_{j \in \{q.C2\}} \alpha(i, j; q) B_{ijp} m_i m_j
\]

\[
\begin{align*}
&= \sum_{q \in B} \left( \sum_{p \in B \cap \{q.C1\}} \sum_{p \in B \cap \{q.C2\}} G r_q \beta_i(r_p, r_q) \sum_{i \in \{q.C1\}} \sum_{j \in \{q.C2\}} \alpha(i, j; q) B_{ijp} m_i m_j \right) \\
&\quad + \sum_{q \in B} \sum_{p \in B \cap \{q.C1\}} G r_q \beta_i(r_p, r_q) \sum_{i \in \{p.C1\}} \sum_{j \in \{p.C2\}} \alpha(i, j; q) B_{ijp} m_i m_j
\end{align*}
\]

Here, we explicitly wrote the summations of \( p \) over the children of \( q \) into summations over child 1 and 2 of \( q \). If \( p \) sums over \( \{q.C1\} \), then \( B_{ijp} = 0 \) unless \( i \in \{q.C1\} \) is a descendant of \( p \) (cf. Appendix A1.1). Conversely, if \( p \) sums over \( \{q.C2\} \), then \( B_{ijp} = 0 \) unless \( j \in \{q.C2\} \) is a descendant of \( p \). Therefore, either summations of \( i \) and \( j \) over the children of \( q \) can be rewritten as summations over the descendants of binary \( p \), i.e.

\[
S'_i = \sum_{q \in B} \sum_{p \in B \cap \{q.C1\}} \sum_{p \in B \cap \{q.C2\}} G r_q \beta_i(r_p, r_q) \sum_{i \in \{p.C1\}} \sum_{j \in \{p.C2\}} \alpha(i, j; q) B_{ijp} m_i m_j + \sum_{q \in B} \sum_{p \in B \cap \{q.C1\}} G r_q \beta_i(r_p, r_q) \sum_{i \in \{p.C1\}} \sum_{j \in \{p.C2\}} \alpha(i, j; q) B_{ijp} m_i m_j
\]

\[
\begin{align*}
&= \sum_{q \in B} \sum_{p \in B \cap \{q.C1\}} G r_q \beta_i(r_p, r_q) \sum_{i \in \{p.C1\}} \sum_{j \in \{p.C2\}} \alpha(i, j; q) B_{ijp} m_i m_j + \sum_{q \in B} \sum_{p \in B \cap \{q.C1\}} G r_q \beta_i(r_p, r_q) \sum_{i \in \{p.C1\}} \sum_{j \in \{p.C2\}} \alpha(i, j; q) B_{ijp} m_i m_j
\end{align*}
\]

In the last line, we used that in the terms where the outermost summation runs over \( i \), \( i \) runs over the descendants of \( p \), therefore \( \alpha(i, j; q) \) is equivalent to \( \alpha(p, j; q) \); the same applies when the outermost summation runs over \( j \), in which case \( \alpha(i, j; q) \) is equivalent to \( \alpha(i, p; q) \). Focusing on these outermost summations over children of \( p \), we split the outermost summation over the children of \( p \); using the properties of \( B_{ijp} \) (cf. Appendix A1.1), we find

\[
\sum_{i \in \{p.C1\}} B_{ijp} m_i = \sum_{i \in \{p.C1\}} B_{ijp} m_i + \sum_{i \in \{p.C2\}} B_{ijp} m_i = \sum_{i \in \{p.C1\}} m_i \frac{\alpha(p.C1, q.C2; p) M_{p.C2}}{M_p} + \sum_{i \in \{p.C2\}} m_i \frac{\alpha(p.C2, q.C2; p) M_{p.C1}}{M_p}
\]

\[
\begin{align*}
&= \frac{\alpha(p.C1, q.C2; p) M_{p.C2}}{M_p} \sum_{i \in \{p.C1\}} m_i - \frac{\alpha(p.C1, q.C2; p) M_{p.C1}}{M_p} \sum_{i \in \{p.C2\}} m_i
\end{align*}
\]

\[
= \frac{\alpha(p.C1, q.C2; p) M_{p.C2}}{M_p} M_{p.C1} - \frac{\alpha(p.C1, q.C2; p) M_{p.C1}}{M_p} M_{p.C1} = 0,
\]

where we used that \( \alpha(p.C1, q.C2; p) = -\alpha(p.C2, q.C2; p) \). By the same arguments,

\[
\sum_{j \in \{p.C1\}} B_{ijp} m_j = 0.
\]

This shows that \( S'_i = 0 \).

### A4.3 Quadrupole-order term

In the summations of the ‘quadrupole-order’ term \( S'_2 \) (cf. equation A20), the individual terms contain, in principle, three different binaries. We show that only terms with binary pairs remain, significantly simplifying the expression. Using equation (A40) to rewrite the summations of pairs of bodies, and using similar arguments as in Appendix A4.2, we find

\[
-S'_2 = \sum_{i \neq j} \sum_{m \in B} G m_i m_j r_m \frac{1}{2} \sum_{p \in B} \sum_{q \in B} B_{ijp} B_{ijq} \beta_2(r_p, r_q, r_m) = \sum_{i \neq j} \sum_{k \in \{k.C1\}} \sum_{l \in \{k.C2\}} \frac{G m_i m_j}{r_k} \sum_{p \in B} \sum_{q \in B} B_{ijp} B_{ijq} \beta_2(r_p, r_q, r_k)
\]

\[
= \frac{1}{2} \sum_{i \neq j} \sum_{k \in \{k.C1\}} \sum_{l \in \{k.C2\}} \sum_{p \in B} \sum_{q \in B} G m_i m_j \frac{1}{r_k} B_{ijp} B_{ijq} \beta_2(r_p, r_q, r_k)
\]

\[
= \frac{1}{2} \sum_{i \neq j} \sum_{k \in \{k.C1\}} \sum_{l \in \{k.C2\}} \sum_{p \in B} \sum_{q \in B} G m_i m_j \frac{1}{r_k} B_{ijp} B_{ijq} \beta_2(r_p, r_q, r_k)
\]

\[
= \frac{1}{2} \sum_{i \neq j} \sum_{k \in \{k.C1\}} \sum_{l \in \{k.C2\}} \sum_{p \in B} \sum_{q \in B} G m_i m_j \frac{1}{r_k} \beta_2(r_p, r_q, r_k) \sum_{i \in \{k.C1\}} \sum_{j \in \{k.C2\}} m_i m_j B_{ijp} B_{ijq}
\]

\[
\text{MNRAS 459, 2827–2874 (2016)}
\]
\[
\frac{1}{2} \sum_{k \in B} \sum_{p \in B} \sum_{q \in B} \frac{G}{r_k} \beta_2(r_p, r_q, r_k) \sum_{j \in \{k, C2\}} m_j \sum_{i \in \{p, C\}} m_i B_{ijp} B_{ijq} = R_1,
\]
\[
\frac{1}{2} \sum_{k \in B} \sum_{p \in \{k, C2\}} \sum_{q \in \{k, C2\}} \frac{G}{r_k} \beta_2(r_p, r_q, r_k) \sum_{j \in \{k, C2\}} m_j \sum_{i \in \{p, C\}} m_i B_{ijp} B_{ijq} = R_2.
\]

In the last line, we split the summation of \( p \in \{k, C\}\) into separate summations over child \( n \) of \( k \), and we denote the corresponding terms with \( R_n \). Alternatively, because the expression is fully symmetric with respect to \( p \) and \( q \) (note that \( \beta_2(r_p, r_q, r_k) = \beta_2(r_p, r_q, r_k) \)), the split can also be applied to the summation of \( q \in \{k, C\}\).

The following arguments apply similarly to \( R_1 \) and \( R_2 \); here, we specify to \( R_1. B_{ijq} = 0 \) if \( q \neq B_p(i, j) \). Because \( i \in \{p, C\}\), this implies that for non-zero terms,

(i) \( q = p \) or
(ii) \( q \neq p \) with
   (a) \( p \in \{q, C\}\),
   (b) \( q \in \{p, C\}\) or
   (c) \( q \in \{k, C2\}\).

We address these cases below individually, starting with the case \( q \neq p \) first.

(ii) (a) \( q \neq p \) and \( p \in \{q, C\} \). In this case, \( B_{ijq} \) in the summation of \( i \in \{p, C\} \) is constant, and is given by

\[
B_{ijq} = \alpha(p, j; q) \frac{M_{p, C(p)}}{M_q}.
\]

Therefore, \( B_{ijq} \) can be taken outside of the summation of \( i \in \{p, C\} \), i.e.

\[
\sum_{i \in \{p, C\}} m_i B_{ijp} B_{ijq} = B_{ijq} \sum_{i \in \{p, C\}} m_i B_{ijp} = 0,
\]

where the last property was shown explicitly in equation (A44). In other words, the terms associated with case (ii) (a) cancel.

(ii) (b) \( q \neq p \) and \( q \in \{p, C\} \). If \( q \in \{p, C\} \), then \( B_{ijq} \neq 0 \) only if \( i \in \{q, C\} \). Furthermore, \( B_{ijp} \) is constant, giving

\[
\sum_{i \in \{p, C\}} m_i B_{ijp} B_{ijq} = B_{ijp} \sum_{i \in \{q, C\}} m_i B_{ijq} = 0,
\]

where we again used equation (A44). Therefore, the terms associated with case (ii) (b) cancel as well.

(ii) (c) \( q \neq p \) and \( q \in \{k, C2\} \). Note that in the case of \( R_1, j \in \{k, C2\}. If q \in \{k, C2\}, then B_{ijq} \neq 0 \) only if \( j \in \{q, C\} \). Furthermore, \( B_{ijp} \) is constant when summing over \( j \), whereas \( B_{ijq} \) is constant when summing over \( i \in \{p, C\} \). Therefore,

\[
\sum_{j \in \{k, C2\}} \sum_{i \in \{p, C\}} m_j B_{ijp} B_{ijq} = \left( \sum_{i \in \{p, C\}} m_i B_{ijp} \right) \left( \sum_{j \in \{q, C\}} m_j B_{ijq} \right) = 0,
\]

showing that terms associated with case (ii) (c) are zero.

(i) \( q = p \). In the case \( q = p \), the associated terms do not cancel. The double summation over \( p \) and \( q \) reduces to a single summation and \( B_{ijq} = B_{ijp} \), hence

\[
R_1 = \frac{1}{2} \sum_{k \in B} \sum_{p \in \{k, C\}} \sum_{q \in \{k, C\}} \frac{G}{r_k} \beta_2(r_p, r_q, r_k) \sum_{j \in \{k, C2\}} m_j \sum_{i \in \{p, C\}} m_i B_{ijp}^2.
\]

The outermost summation of \( i \in \{p, C\} \) does not cancel, and evaluates to

\[
\sum_{i \in \{p, C\}} m_i B_{ijp}^2 = \left( \sum_{i \in \{p, C\}} m_i B_{ijp} \right)^2 = \frac{[\alpha(p, C1, k, C2; p)]^2 M_{p, C2}^2}{M_p^2} \sum_{i \in \{p, C\}} m_i + \frac{[\alpha(p, C2, k, C2; p)]^2 M_{p, C1}^2}{M_p^2} \sum_{i \in \{p, C\}} m_i
\]

\[
= M_{p, C2}^2 M_{p, C1} + M_{p, C1}^2 M_{p, C2} M_p^2 = \frac{M_{p, C1} M_{p, C2}}{M_p}.
\]
The latter expression is independent of \( j \) and can therefore be taken in front of the summation of \( j \in \{ k, C2 \} \). Therefore,

\[
R_1 = \frac{1}{2} \sum_{k \in B} \sum_{p \in \{ k, C1 \}} \sum_{m = 0}^{\infty} \frac{M_{pC1}M_{pC2}}{M_p} \frac{G}{r_k} \beta_2(r_p, r_p, r_k) \sum_{j \in \{ k, C2 \}} m_j = \frac{1}{2} \sum_{k \in B} \sum_{p \in \{ k, C1 \}} \sum_{m = 0}^{\infty} \frac{M_{pC1}M_{pC2}}{M_p} \frac{GM_{kC2}}{r_k} \beta_2(r_p, r_p, r_k)
\]

\[
= \frac{1}{2} \sum_{k \in B} \sum_{p \in \{ k, C1 \}} \frac{M_{pC1}M_{pC2}}{M_p} \frac{GM_{kCS(p)}}{r_k} \beta_2(r_p, r_p, r_k),
\]

(A53)

where, as before, we used the notation \( M_{kCS(p)} \) to denote the mass of the child of \( k \) that is the sibling of the child of \( k \) that is connected to \( p \) (cf. Appendix A1).

The same arguments apply to \( R_2 \), in which case \( p \in \{ k, C2 \} \). The result is

\[
R_2 = \frac{1}{2} \sum_{k \in B} \sum_{p \in \{ k, C2 \}} \frac{M_{pC1}M_{pC2}}{M_p} \frac{GM_{kCS(p)}}{r_k} \beta_2(r_p, r_p, r_k).
\]

(A54)

Adding \( R_1 \) and \( R_2 \), writing the separate summations of \( p \in \{ k, C1 \} \) and \( p \in \{ k, C2 \} \) again as a single summation of \( p \in \{ k, C \} \), and substituting the explicit expression for \( \beta_2 \) (cf. equation A25), we find the final simplified expression for the quadrupole-order term,

\[
-S_2 = R_1 + R_2 = \frac{1}{2} \sum_{k \in B} \sum_{p \in \{ k, C \}} \sum_{q \in \{ k, C \}} \sum_{i \in \{ k, C \}} \sum_{j \in \{ k, C \}} \frac{M_{pC1}M_{pC2}}{M_p} \frac{GM_{kCS(p)}}{r_k} \left( \frac{r_p}{r_k} \right)^2 \left[ 3(\hat{r}_p \cdot \hat{r}_k)^2 - 1 \right].
\]

(A55)

Therefore, the quadrupole-order term can be written as a double sum over binaries, where one of the binaries is a descendant of the other. As a consequence of the topology of the system and the resulting properties of the quantity \( B_{ijk} \) all the terms depending on three different binaries cancel. Only terms with \( p = q \) survive, and the resulting quadrupole-order terms individually only depend on two binary separation vectors.

The mathematical form of each of these terms is identical to the quadrupole-order term in the hierarchical three-body system. In particular, the ‘angular part’ \((1/2)[3(\hat{r}_p \cdot \hat{r}_k)^2 - 1]\) in equation (A55) is the same as the second Legendre polynomial \( P_2(x) = (1/2)(3x^2 - 1) \) with \( x = \cos(\theta_{pq}) \) the cosine of the angle between the ‘inner’ and ‘outer’ separation vectors \( r_p \) and \( r_k \), respectively, that appears in the hierarchical three-body Hamiltonian (Harrington 1968). In other words, at quadrupole order, the Hamiltonian of the hierarchical \( N \)-body system can be constructed from the three-body Hamiltonian.

### A4.4 Octupole-order term

For the ‘octupole-order’ term \( S_3 \) (cf. equation A21), the individual terms contain, in principle, four different binaries. After rewriting, we find that terms with binary pairs and triplets remain; terms depending on quadruples cancel. Following similar steps as in Appendix A4.3,

\[
S_3 = \sum_{i \in \{ k, C \}} \sum_{j \in \{ k, C \} \setminus \{ i \}} \sum_{m = 0}^{\infty} \frac{Gm_km_j}{r_k} \frac{1}{2} \alpha(i, j; m) \sum_{p \in B} \sum_{q \in B} \sum_{u \in B} B_{ijp}B_{ijq}B_{iju} \beta_3(r_p, r_q, r_u, r_m)
\]

\[
= \sum_{k \in B} \sum_{i \in \{ k, C1 \}} \sum_{j \in \{ k, C2 \}} \sum_{m = 0}^{\infty} \frac{Gm_km_j}{r_k} \frac{1}{2} \alpha(i, j; k) \sum_{p \in B} \sum_{q \in B} \sum_{u \in B} B_{ijp}B_{ijq}B_{iju} \beta_3(r_p, r_q, r_u, r_k)
\]

\[
= \frac{1}{2} \sum_{k \in B} \sum_{i \in \{ k, C1 \}} \sum_{j \in \{ k, C2 \}} \sum_{m = 0}^{\infty} \sum_{p \in B} \sum_{q \in B} \sum_{u \in B} \frac{G}{r_k} \beta_3(r_p, r_q, r_u, r_k) \alpha(i, j; k) m_k m_j B_{ijp}B_{ijq}B_{iju}.
\]

As before, we split the summation of \( p \in \{ k, C \} \) into two summations, \( R_1 \) and \( R_2 \), over the children of \( k \) (\( q \) and \( u \) being equally valid choices). In the case of \( R_1 \),

\[
R_1 = \frac{1}{2} \sum_{k \in B} \sum_{i \in \{ k, C1 \}} \sum_{j \in \{ k, C2 \}} \sum_{m = 0}^{\infty} \sum_{p \in B} \sum_{q \in B} \sum_{u \in B} \frac{G}{r_k} \beta_3(r_p, r_q, r_u, r_k) \sum_{c \in \{ k, C \}} \alpha(i, j; k) m_k m_j B_{ijp}B_{ijq}B_{iju}
\]

\[
= \frac{1}{2} \sum_{k \in B} \sum_{i \in \{ k, C1 \}} \sum_{j \in \{ k, C2 \}} \sum_{m = 0}^{\infty} \sum_{p \in B} \sum_{q \in B} \sum_{u \in B} \frac{G}{r_k} \beta_3(r_p, r_q, r_u, r_k) \sum_{j \in \{ k, C2 \}} m_j \alpha(p, j; k) m_i B_{ijp}B_{ijq}B_{iju},
\]

(A56)

where we used that \( \alpha(i, j; k) = \alpha(p, j; k) \) is constant in the summation of \( i \in \{ p, C \} \). The triple summations of \( p, q \) and \( u \) can be divided into the following five main cases, with several subcases. The subcases are those for which the corresponding \( B_{ijp}, B_{ijq}, \text{etc.} \) are non-zero. Specifying to \( R_1 \) (i.e. \( p \in \{ k, C1 \} \)), the cases are as follows.

(i) \( u = q = p \);
(ii) \( q = p \) & \( u \neq q \) with
(a) \( p \in \{ u, C \} \),
(b) \( u \in \{ p, C \} \) or
(c) \( u \in \{ k, C \} \);

(iii) \( u = p \neq q \) with
(a) \( p \in \{ q, C \} \),
(b) \( q \in \{ p, C \} \) or
(c) \( q \in \{ k, C \} \);

(iv) \( u = q \neq p \) with
(a) \( p \in \{ u, C \} \),
(b) \( u \in \{ p, C \} \) or
(c) \( u \in \{ k, C \} \);

(v) \( u \neq q \neq p \) with
(a) \( p \in \{ q, C \} \) & \( p \in \{ u, C \} \),
(b) \( p \in \{ q, C \} \) & \( u \in \{ p, C \} \),
(c) \( p \in \{ q, C \} \) & \( u \in \{ k, C \} \),
(d) \( q \in \{ p, C \} \) & \( p \in \{ u, C \} \),
(e) \( q \in \{ p, C \} \) & \( u \in \{ p, C \} \),
(f) \( q \in \{ p, C \} \) & \( u \in \{ k, C \} \),
(g) \( q \in \{ k, C \} \) & \( p \in \{ u, C \} \),
(h) \( q \in \{ k, C \} \) & \( u \in \{ p, C \} \),
(i) \( q \in \{ k, C \} \) & \( u \in \{ k, C \} \),
(j) \( u \in \{ p, C \} \) & \( q \in \{ p, C \} \) or
(k) \( u \in \{ p, C \} \) & \( q \in \{ k, C \} \).

(i) \( u = q = p \). With \( u = q = p \), the corresponding outermost summation in \( R_1 \) becomes

\[
\sum_{i \in \{ p, C \}} m_i B_{ijp}^3 = \left( \sum_{i \in \{ p, C \}} + \sum_{i \in \{ p, C \}} \right) m_i B_{ijp}^3 = \frac{[\alpha(p, C_1, k, C_2; p)]^3}{M_p^3} M_{p, C_2} \sum_{i \in \{ p, C \}} m_i + \frac{[\alpha(p, C_2, k, C_2; p)]^3}{M_p^3} M_{p, C_1} \sum_{i \in \{ p, C \}} m_i
\]

\[
= \frac{M_{p, C_1} M_{p, C_2} \alpha(p, C_1, k, C_2; p) M_{p, C_2} - M_{p, C_1}}{M_p}
\]

The contribution to \( R_1 \) due to case (i) is, therefore,

\[
R_{1(i)} = \frac{1}{2} \sum_{k \in B} \sum_{p \in B} \sum_{p \in \{ k, C \}} G \frac{\beta_3(r_p, r_p, r_p, r_k)}{r_k} \sum_{j \in \{ k, C \}} m_j \alpha(p, j; k) \frac{M_{p, C_1} M_{p, C_2}}{M_p} \frac{\alpha(p, C_1, k, C_2; p) M_{p, C_2} - M_{p, C_1}}{M_p}
\]

\[
= \frac{1}{2} \sum_{k \in B} \sum_{p \in B} \sum_{p \in \{ k, C \}} \frac{M_{p, C_1} M_{p, C_2}}{M_p} \alpha(p, C_1, k, C_2; p) \frac{M_{p, C_2} - M_{p, C_1}}{M_p} \alpha(p, k, C_2; k) \beta_3(r_p, r_p, r_p, r_k)
\]

\[
= \frac{1}{2} \sum_{k \in B} \sum_{p \in B} \sum_{p \in \{ k, C \}} \frac{G M_{p, C_2}}{r_k} \beta_3(r_p, r_p, r_p, r_k).
\]

A similar result holds for \( R_{2(i)} \), i.e.

\[
R_{2(i)} = \frac{1}{2} \sum_{k \in B} \sum_{p \in B} \sum_{p \in \{ k, C \}} \frac{M_{p, C_1} M_{p, C_2}}{M_p} \alpha(p, C_1, k, C_2; p) \frac{M_{p, C_2} - M_{p, C_1}}{M_p} \alpha(p, k, C_2; k) \frac{G M_{p, C_2}}{r_k} \beta_3(r_p, r_p, r_p, r_k).
\]

and, therefore,

\[
R_0 = R_{1(i)} + R_{2(i)} = \frac{1}{2} \sum_{k \in B} \sum_{p \in B} \sum_{p \in \{ k, C \}} \frac{M_{p, C_1} M_{p, C_2}}{M_p} \alpha(p, C_1, k, C_2; p) \frac{M_{p, C_2} - M_{p, C_1}}{M_p} \alpha(p, k, C_2; k) \frac{G M_{p, C_2}}{r_k} \left( \frac{r_p}{r_k} \right)^3
\]

\[
\times \left[ \beta_3^3 - 3(\beta_3 - \hat{\beta}_3) \right],
\]

where we substituted the explicit expression for \( \beta_3 \) using equation (A26).
Note the presence of the ‘sign quantities’ \( \alpha \) in \( R_{1(iii)} \) and \( R_{2(iii)} \). They appear because reversing the definition of the direction of \( r_p \) and \( r_k \), i.e. \( r_p' = -r_p \) and \( r_k' = -r_k \), should not change the new expressions in terms of the primed vectors. The minus signs arising from the redefinition are absorbed into the new quantities \( \alpha' \), which also change sign. A similar argument applies to the mass difference term \( M_{p,C2} - M_{p,C1} \) (see also Appendix A5.2).

(ii) (a) \( q = p & u \neq q & p \in \{ u.C \} \). While summing over \( i \in \{ p.C \} \), \( B_{iju} \) is constant, giving

\[
\sum_{i \in \{ p.C \}} m_i B_{ijp} B_{iju} = \frac{\alpha(p, k.C2; u) M_{p,C1} M_{p,C2}}{M_p} \alpha(p, k.C2; u) M_{p,C1} M_{p,C2},
\]

where we used equation (A52).

(ii) (b) \( q = p & u \neq q & u \in \{ p.C \} \). While summing over \( i \in \{ p.C \} \), \( B_{ijp} \) is constant, and \( B_{iju} \neq 0 \) only if \( i \in \{ u.C \} \). Therefore,

\[
\sum_{i \in \{ p.C \}} m_i B_{ijp} B_{iju} = B_{ijp} \sum_{i \in \{ u.C \}} m_i B_{iju} = 0,
\]

where the last step follows from equation (A44).

(ii) (c) \( q = p & u \neq q & u \in \{ k.C2 \} \). While summing over \( i \in \{ p.C \} \), \( B_{ijp} \) is constant, whereas \( B_{iju} \) is constant while summing over \( j \in \{ k.C2 \} \). Furthermore, \( B_{iju} \neq 0 \) only if \( j \in \{ u.C \} \). This implies

\[
\sum_{j \in \{ k.C2 \}} \sum_{i \in \{ p.C \}} m_j \sum_{i \in \{ u.C \}} \alpha(p, p, j; k) M_{p,C1} M_{p,C2} \frac{G_{ijp}}{r_k} \beta_3(r_p, r_p, r_u, r_k) \sum_{i \in \{ u.C \}} m_i \alpha(p, p, j; k) M_{p,C1} M_{p,C2} \frac{G_{ijp}}{r_k} \beta_3(r_p, r_p, r_u, r_k)
\]

\[
= \frac{1}{2} \sum_{k \in \{ k.C2 \}} \sum_{p \in \{ p.B \}} \sum_{u \in \{ u.C \}} \sum_{p \in \{ p.C \}} \sum_{u \in \{ u.C \}} M_{p,C1} M_{p,C2} M_{p,C1} M_{p,C2} \frac{G_{ijp}}{r_k} \beta_3(r_p, r_p, r_u, r_k) \alpha(p, p, j; k) M_{p,C1} M_{p,C2} \frac{G_{ijp}}{r_k} \beta_3(r_p, r_p, r_u, r_k)
\]

\[
= \frac{1}{2} \sum_{k \in \{ k.C2 \}} \sum_{p \in \{ p.B \}} \sum_{u \in \{ u.C \}} \sum_{p \in \{ p.C \}} \sum_{u \in \{ u.C \}} M_{p,C1} M_{p,C2} M_{p,C1} M_{p,C2} \frac{G_{ijp}}{r_k} \beta_3(r_p, r_p, r_u, r_k) \alpha(p, p, j; k) M_{p,C1} M_{p,C2} \frac{G_{ijp}}{r_k} \beta_3(r_p, r_p, r_u, r_k)
\]

\[
\times \left[ 5(\hat{r}_p \cdot \hat{r}_k)^2(\hat{r}_u \cdot \hat{r}_k) - 2(\hat{r}_p \cdot \hat{r}_k)(\hat{r}_p \cdot \hat{r}_u) - (\hat{r}_u \cdot \hat{r}_k) \right].
\]

A similar result applies to \( R_{2(iii)} \). This gives

\[
R_{(iii)} = R_{1(iii)} + R_{2(iii)} = \frac{1}{2} \sum_{k \in \{ k.C2 \}} \sum_{p \in \{ p.B \}} \sum_{u \in \{ u.C \}} \sum_{p \in \{ p.C \}} \sum_{u \in \{ u.C \}} M_{p,C1} M_{p,C2} M_{p,C1} M_{p,C2} \frac{G_{ijp}}{r_k} \beta_3(r_p, r_p, r_u, r_k) \alpha(p, p, j; k) M_{p,C1} M_{p,C2} \frac{G_{ijp}}{r_k} \beta_3(r_p, r_p, r_u, r_k)
\]

\[
\times \left[ 5(\hat{r}_p \cdot \hat{r}_k)^2(\hat{r}_u \cdot \hat{r}_k) - 2(\hat{r}_p \cdot \hat{r}_k)(\hat{r}_p \cdot \hat{r}_u) - (\hat{r}_u \cdot \hat{r}_k) \right].
\]

Note that the sign quantities \( \alpha(p, k.CS(p); k) \) and \( \alpha(p, k.CS(p); u) \) ensure invariance with respect to the definition of the directions of \( r_k \) and \( r_u \), respectively.

(iii) (a,b,c) \( u = p & q \neq u \). This case is completely analogous to case (ii), now with the roles of \( q \) and \( u \) reversed. Note that \( \beta_3 \) satisfies \( \beta_3(r_p, r_p, r_u, r_k) = \beta_3(r_p, r_p, r_u, r_k) \). Therefore, \( R_{(iii)} = R_{(iii)} \).

The case (iv) also turns out to satisfy \( R_{(iv)} = R_{(iii)} \), although the equality of \( R_{(iv)} \) to \( R_{(iii)} \) and \( R_{(iv)} \) is not immediately clear. For this reason, we treat this case in detail.

(iv) (a) \( u = q & p \neq u & p \in \{ u.C \} \). While summing over \( i \in \{ p.C \} \), \( B_{iju} \) is constant, giving

\[
\sum_{i \in \{ p.C \}} m_i B_{ijp} B_{iju} = B_{ijp} \sum_{i \in \{ p.C \}} m_i B_{iju} = 0.
\]
(iv) (b) If \( q = p \neq u \) and \( u \in \{p,C\} \). While summing over \( i \in \{p,C\} \), \( B_{ju} \neq 0 \) only if \( i \in \{u,C\} \), and \( B_{ip} \) is constant. Therefore,

\[
\sum_{i \in \{p,C\}} \sum_{k} m_i B_{ij}^2 B_{ji}^2 = \sum_{i \in \{u,C\}} m_i B_{ij}^2 = \alpha(u, k.C2; p) \frac{M_p M_a C_1 M_a C_2}{M_u}.
\]

(A67)

In this case, \( \alpha(i, j; k) = \alpha(u, k.C2; k) \).

(iv) (c) If \( q = p \neq u \) and \( u \in \{k,C2\} \). While summing over \( i \in \{p,C\} \), \( B_{ju} \) is constant, whereas \( B_{ip} \) is constant while summing over \( j \in \{k,C2\} \). Furthermore, \( B_{ju} \neq 0 \) only if \( j \in \{u,C\} \). This implies

\[
\sum_{j \in \{k,C2\}} \sum_{i \in \{p,C\}} m_j B_{ij}^2 B_{ji}^2 = \left( \sum_{j \in \{u,C\}} m_j B_{ij}^2 \right) \left( \sum_{i \in \{p,C\}} m_i B_{ij}^2 \right) = 0.
\]

(A68)

Specifying to \( R_1 \), the total contribution due to case (iv) is

\[
R_{1(iv)} = \frac{1}{2} \sum_{k \in B} \sum_{p \in \{k,C1\}} \sum_{u \in \{k,C\}} \frac{G}{r_k} \beta_3 (r_p, r_u, r_u, r_k) \sum_{j \in \{k,C2\}} m_j \alpha(u, k.C2; k) \frac{M_a C_1 M_a C_2}{M_u} \frac{\alpha(u, k.C2; p) M_p C_1 M_p C_2}{M_p} \beta_3 (r_p, r_u, r_u, r_k).
\]

(A69)

This gives

\[
R_{1(iv)} = R_{1(ii)} + R_{1(iv)} = \frac{1}{2} \sum_{k \in B} \sum_{p \in \{k,C1\}} \sum_{u \in \{k,C\}} \frac{M_a C_1 M_a C_2}{M_u} \alpha(u, k.CS(p); k) \frac{M_a C_1 M_a C_2}{M_u} \frac{\alpha(u, k.CS(p); p) M_p C_1 M_p C_2}{M_p} \beta_3 (r_p, r_u, r_u, r_k). \]

(A70)

In equation (A70), \( p, u \in \{k,C\} \) and \( u \in \{p,C\} \). Therefore,

\[
\alpha(u, k.CS(p); k) = \alpha(u, k.CS(u); k);
\]

\[
M_{k.CS(p)} = M_{k.CS(u)};
\]

\[
\alpha(u, k.CS(p); p) = \alpha(u, k.CS(u); p).
\]

(A71)

Inserting these relations into equation (A70) and, subsequently, interchanging \( p \) and \( u \) (i.e. only changing notation), we find

\[
R_{1(iv)} = \frac{1}{2} \sum_{k \in B} \sum_{p \in \{k,C1\}} \sum_{u \in \{k,C\}} \frac{M_a C_1 M_a C_2}{M_u} \alpha(u, k.CS(u); k) \frac{M_a C_1 M_a C_2}{M_u} \frac{\alpha(p, k.CS(p); p) M_p C_1 M_p C_2}{M_p} \beta_3 (r_p, r_u, r_u, r_k).
\]

(A72)

\[
= \frac{1}{2} \sum_{k \in B} \sum_{p \in \{k,C1\}} \sum_{u \in \{k,C\}} \frac{M_p C_1 M_p C_2}{M_p} \alpha(p, k.CS(p); k) \frac{M_a C_1 M_a C_2}{M_u} \frac{\alpha(p, k.CS(p); u) M_{k.CS(p)} M_a C_1 M_a C_2}{M_u} \beta_3 (r_u, r_p, r_p, r_k).
\]

(A73)

\[
= \frac{1}{2} \sum_{k \in B} \sum_{p \in \{k,C1\}} \sum_{u \in \{k,C\}} \frac{M_a C_1 M_a C_2}{M_p} \alpha(p, k.CS(p); k) \frac{M_p C_1 M_p C_2}{M_p} \alpha(p, k.CS(p); u) M_{k.CS(p)} \left( \frac{r_p}{r_u} \right)^2 \left( \frac{r_u}{r_k} \right)
\]

(A74)

Note that \( \beta_3 (r_u, r_p, r_p, r_k) = \beta_3 (r_p, r_u, r_u, r_k) \).

To conclude, the non-zero terms from cases (ii), (iii) and (iv) are equal, and so adding them gives \( R_{1(ii)} + R_{1(iii)} + R_{1(iv)} = 3R_{1(ii)} \).
In all subcases listed above, two of the quantities in $B_{ijp}B_{iqj}B_{ju}$ are always constant when summing over a particular binary. Consequently, all terms include the term of the form

$$\sum_{i \in \omega_C} m_i B_{ijw} = 0,$$

where $w$ is any of $p, q$ and $u$. Therefore, all terms associated with $u \neq q$ and $q \neq p$ are zero, i.e. $R_{(v)} = 0$.

We conclude that the octupole-order term can be written as

$$S_3 = R_{(i)} + R_{(ii)} + R_{(iii)} + R_{(iv)} + R_{(v)}$$

$$= \frac{1}{2} \sum_{k \in B} \sum_{p \in \beta(k.C)} \frac{M_{p.C1} M_{p.C2}}{M_p} \alpha(p, C1, k.CS(p); p) \frac{M_{p.C2} - M_{p.C1}}{M_p} \alpha(p, k.CS(p); k) \frac{GM_{k.CS(p)}(r_k)}{r_k} \left( \frac{r_p}{r_k} \right)^3 \left[ 5(\hat{r}_p \cdot \hat{r}_k)^3 - 3(\hat{r}_p \cdot \hat{r}_k) \right]$$

$$+ \frac{3}{2} \sum_{k \in B} \sum_{p \in \beta(k.C)} \frac{M_{p.C1} M_{p.C2}}{M_p} \alpha(p, k.CS(p); k) \frac{GM_{k.CS(p)}(r_k)}{r_k} \alpha(p, k.CS(p); u) M_{u.CS(p)} \left( \frac{r_p}{r_k} \right)^3 \left( \frac{r_u}{r_k} \right)^2 \left[ 5(\hat{r}_p \cdot \hat{r}_k)^3 - 3(\hat{r}_p \cdot \hat{r}_k) \right].$$

The first major term consists of binary pair terms, and is mathematically equivalent to the octupole-order term in the hierarchical three-body problem. The second major term consists of binary triplet terms, and is mathematically equivalent to the octupole-order ‘cross term’ in the hierarchical four-body problem (‘3+1’ configuration), which was derived previously by Hamers et al. (2015, cf. equation A7d of the latter paper).

### A4.5 Hexadecupole-order term (pairwise)

Extrapolating the above results, at the ‘hexadecupole’ order, i.e. $O(x^4)$, terms in the Hamiltonian after rewriting contain terms depending on binary pairs, triplets and quadruplets. For all these combinations, the binaries need to be connected for the terms to be non-vanishing. Furthermore, terms depending on five binaries, i.e. quintlet terms, vanish because of the property equation (A44).

Using equation (A40), $S_4'$ (cf. equation A22) is given by

$$-S_4' = \sum_{i \neq j} \sum_{m} \frac{Gm_i m_j}{r_{ik}} \frac{1}{2} \sum_{p \in \beta(k.C)} \sum_{q \in \beta(k.C)} \sum_{v \in \beta(k.C)} B_{ijp} B_{ijq} B_{ijv} \beta_4(\hat{r}_p, \hat{r}_q, \hat{r}_v, \hat{r}_k).$$

$$= \sum_{k \in B} \sum_{i \in \beta(k.C)} \sum_{j \in \beta(k.C)} \sum_{m} \frac{Gm_i m_j}{r_{ik}} \frac{1}{2} \sum_{p \in \beta(k.C)} \sum_{q \in \beta(k.C)} \sum_{v \in \beta(k.C)} B_{ijp} B_{ijq} B_{ijv} \beta_4(\hat{r}_p, \hat{r}_q, \hat{r}_v, \hat{r}_k).$$

$$= \frac{1}{8} \sum_{k \in B} \sum_{i \in \beta(k.C)} \sum_{j \in \beta(k.C)} \sum_{m} \frac{Gm_i m_j}{r_{ik}} \beta_4(\hat{r}_p, \hat{r}_q, \hat{r}_v, \hat{r}_k) \sum_{i \in \beta(k.C)} \sum_{j \in \beta(k.C)} m_i m_j B_{ijp} B_{ijq} B_{ijv} B_{ijv}.$$
The outermost summation over bodies, in the case of \( i \in \{ p, C \} \), is given by

\[
\sum_{i \in \{ p, C \}} m_i B^4_{ij;p} = \left( \sum_{i \in \{ p, C \}} m_i + \sum_{i \in \{ p, C \}} m_i \right) B^4_{ij;p} = \left( \sum_{i \in \{ p, C \}} m_i + \sum_{i \in \{ p, C \}} m_i \right) \frac{[\alpha(p, C_1, k, C_2; p)]^4 M^4_{p, C_2}}{M^4_p} = \sum_{i \in \{ p, C \}} m_i + \sum_{i \in \{ p, C \}} m_i \frac{[\alpha(p, C_2, k, C_2; p)]^4 M^4_{p, C_1}}{M^4_p}.
\]

The same result applies to the summation of \( j \in \{ p, C \} \). We conclude that \( S^4_{k,2} \) is given by

\[
S^4_{k,2} = \frac{1}{8} \sum_{k \in B} \sum_{p \in \{ p, C \}} \frac{M_p M_{p, C_1} M_{p, C_2}}{M_p} \frac{M^2_{p, C_1} + M^2_{p, C_2} + M^2_{p}}{M^3_p} G M_{k, C_3, p} \frac{\beta_5}{r_k} \beta_5(r_p, r_p, r_p, r_p, r_p, \ldots)
\]

\[
= \frac{1}{8} \sum_{k \in B} \sum_{p \in \{ p, C \}} \sum_{q \in \{ p, C \}} \sum_{u \in \{ p, C \}} \sum_{v \in \{ p, C \}} \sum_{w \in \{ p, C \}} B_{ij;p} B_{ij;q} B_{ij;u} B_{ij;v} B_{ij;w} \beta_5(r_p, r_p, r_p, r_p, r_u, r_v, r_w, r_k)
\]

\[
= \frac{1}{8} \sum_{k \in B} \sum_{p \in \{ p, C \}} \sum_{q \in \{ p, C \}} \sum_{u \in \{ p, C \}} \sum_{v \in \{ p, C \}} \sum_{w \in \{ p, C \}} \frac{G_r}{r_k} \beta_5(r_p, r_q, r_u, r_v, r_w, r_k) \sum_{i \in \{ p, C \}} \sum_{j \in \{ p, C \}} \alpha(i, j; k) m_i m_j B^4_{ij;p}
\]

\[
= S^4_{k,3} + S^4_{k,4} + S^4_{k,5},
\]

with

\[
S^4_{k,2} = \frac{1}{8} \sum_{k \in B} \sum_{p \in \{ p, C \}} \frac{G_r}{r_k} \beta_5(r_p, r_p, r_p, r_p, r_p, \ldots) \sum_{j \in \{ p, C \}} m_j \sum_{i \in \{ p, C \}} m_i B^4_{ij;p}
\]

\[
= \frac{1}{8} \sum_{k \in B} \sum_{p \in \{ p, C \}} \frac{G_r}{r_k} \beta_5(r_p, r_p, r_p, r_p, r_p, r_k) \alpha(p, k, C_2; k) \sum_{j \in \{ p, C \}} m_j \sum_{i \in \{ p, C \}} m_i B^4_{ij;p}
\]

\[
+ \frac{1}{8} \sum_{k \in B} \sum_{p \in \{ p, C \}} \frac{G_r}{r_k} \beta_5(r_p, r_p, r_p, r_p, r_p, r_k) \alpha(p, k, C_1; k) \sum_{j \in \{ p, C \}} m_j \sum_{i \in \{ p, C \}} m_i B^4_{ij;p}.
\]

The outermost summation over bodies, in the case of \( i \in \{ p, C \} \), is given by

\[
\sum_{i \in \{ p, C \}} m_i B^5_{ij;p} = \left( \sum_{i \in \{ p, C \}} m_i + \sum_{i \in \{ p, C \}} m_i \right) B^5_{ij;p} = \left( \sum_{i \in \{ p, C \}} m_i + \sum_{i \in \{ p, C \}} m_i \right) \frac{[\alpha(p, C_1, k, C_2; p)]^5 M^5_{p, C_2}}{M^5_p} = \sum_{i \in \{ p, C \}} m_i + \sum_{i \in \{ p, C \}} m_i \frac{[\alpha(p, C_2, k, C_2; p)]^5 M^5_{p, C_1}}{M^5_p}.
\]

\[
= \frac{[\alpha(p, C_1, k, C_2; p)]^5 M^5_{p, C_2} M^5_{p, C_1} + [\alpha(p, C_2, k, C_2; p)]^5 M^5_{p, C_1} M^5_{p, C_2}}{M^5_p} = \alpha(p, C_1, k, C_2; p) M^5_{p, C_1} M^5_{p, C_2} - \frac{M^5_{p, C_2} + M^5_{p, C_1}}{M^5_p}.
\]
The same result holds for $j \in \{p.C\}$. Therefore,

$$S_{k,2} = \frac{1}{8} \sum_{k \in \mathcal{B}} \sum_{p \in \mathcal{B}(k)} \frac{M_{p,C1}M_{p,C2}}{M_p} \alpha(p, C1, p, CS(p); p) \frac{M_{p,C2} - M_{p,C1}}{M_p} \frac{M_{p,C1}^2 + M_{p,C2}^2}{M_p^2} \frac{G M_l \alpha_{p}(\beta(p, r_p, r_p, r_p, r_p))}{r_k} \right) \right] \right).$$

(A85)

4.7 Generalization

In the above appendices, we have shown that $H$ can be written in terms of summations of only binaries, and we have derived explicit expressions for all terms up and including octupole order, and including the binary pair terms at hexadecapole and dotriacontapole order. Here, using similar arguments as before, we generalize these results and derive a formal expression for $S_j$ at arbitrary order $n$ including all binary interactions (i.e. pairwise terms, triplet terms, etc.).

Equations (A29) and (A39) combined read

$$S_j = (-1)^{n+1} \sum_{i < j} \sum_{m \in \mathcal{M}(i, j)} c_{ij} \hat{\beta}_m(r_{a_1}, ..., r_{a_m}, r_l) B_{ij,ja_1}, B_{ij,ja_2}, \ldots, B_{ij,ja_n},$$

(A86)

where we recall that $m = m(i, j)$ denotes the lowest level binary in $B_i(i, j)$. Using equation (A40), we rewrite the summation over pairs of bodies to summations over binaries and children within those binaries, giving

$$S_j = (-1)^{n+1} \sum_{k \in \mathcal{B}} \sum_{i \in \mathcal{B}(k)} \sum_{j \in \mathcal{B}(k)} \frac{G M_{m}m_{j}}{r_k} \alpha(i, j; k) \frac{n}{u_{ij}} \sum_{u_{ij} \in \mathcal{B}(k)} c_{ij} \hat{\beta}_m(r_{a_1}, ..., r_{a_m}, r_l) B_{ij,ja_1}, B_{ij,ja_2}, \ldots, B_{ij,ja_n}.$$  

(A87)

By definition, none of the binaries $u_i$ in the summations $u_1, ..., u_n \in \mathcal{B}$ are the same as binary $k$. Furthermore, because $i \in \{k.C1\}$ and $j \in \{k.C2\}$, if $u_i$ is not part of the children of binary $k$ (i.e. if $u_i \notin \{k.C\}$), then $B_{ij,ja} = 0$. Therefore, the summations $u_1, ..., u_n \in \mathcal{B}$ can be written as summations $u_1, ..., u_n \in \mathcal{B}$ with $u_i \in \{k.C\}$, i.e.

$$S_j = (-1)^{n+1} \sum_{k \in \mathcal{B}} \sum_{i \in \mathcal{B}(k)} \sum_{j \in \mathcal{B}(k)} \frac{G M_{m}m_{j}}{r_k} \alpha(i, j; k) \frac{n}{u_{ij}} \sum_{u_{ij} \in \mathcal{B}(k)} c_{ij} \hat{\beta}_m(r_{a_1}, ..., r_{a_m}, r_l) B_{ij,ja_1}, B_{ij,ja_2}, \ldots, B_{ij,ja_n}.$$  

(A88)

where in the second line, we used that $u_1, ..., u_n$ are (no longer) dependent on $i$ and $j$.

In equation (A88), each binary $u_i$ in the summation $u_1, ..., u_n \in \mathcal{B}$ is associated with a factor $B_{ij,ja}$. A given binary $u_i$ may occur zero to multiple times, up to $n$ times. For example, the pairwise binary terms correspond to $u_1 = \ldots = u_n$, such that there are two unique binaries: $k$ and the equal $a'$. For binary $u_i$, let the number of recurrences be denoted by $d_{a_i}$; generally, $0 \leq d_{a_i} \leq n$. Consequently, the power of $B_{ij,ja}$ is $d_{a_i}$, i.e. the mass ratio factor in $S_j$ associated with binary $u_i$ is $B_{ij,ja}^{d_{a_i}}$.

In the summations $u_1, ..., u_n \in \mathcal{B}$, the binaries $u_1, ..., u_n$ occur in combinations with various divisions over the two children of binary $k$. For a particular combination, let the binaries in child 1 (2) of binary $k$ be denoted by $p_l (q_l)$. Furthermore, for child 1 (2) of $k$, let $p (q)$ denote the binary with the highest level within that child (see below for the case when the highest level within a child of binary $k$ is shared amongst two or more binaries). The number of recurrences associated with binaries $p$ and $q$ are $d_p$ and $d_q$, respectively. Note that if $d_p = 0 (d_q = 0)$, then this implies that there are no binaries in child 1 (2) of binary $k$.

Furthermore, let $n_1, n_2$ denote the combined exponent of all mass ratio quantities $B_{ij,ja}$ associated with child 1 (2) of binary $k$. The allowed values of $n_1$ and $d_p$ are $0 \leq n_1 \leq n$ and $0 \leq n_2 \leq n$, respectively, and because the combined power of all mass ratio factors is $n$, $n_1 + n_2 = n$. For a given non-zero exponent $d_p (d_q)$ of the mass ratio factor associated with binary $p$ ($q$), there are $n_1 - d_p$ ($n_2 - d_q$) binaries in child 1 (2) distinct from $p$ ($q$), such that the combined mass ratio exponent in child 1 (2) is $n_1$ ($n_2$). Note that these $n_1 - d_p$ ($n_2 - d_q$) binaries are not necessarily distinct; each is associated with a recurrence number $d_{a_i}$ ($d_{a_j}$). The maximum recurrence number for binary $p$ ($q$) is $n_1$ ($n_2$).

Subsequently, we rewrite the summations $u_1, ..., u_n \in \mathcal{B}$ as separate summations over the binaries $p, p_1, ..., p_{n_1 - d_p}, q, q_1, ..., q_{n_2 - d_q}$, for all possible combinations of $n_1, n_2, d_p$ and $d_q$. Note that there should only be summations over $p$ and $p_1, ..., p_{n_1 - d_p}, q$ and $q_1, ..., q_{n_2 - d_q}$ if $d_p > 0 (d_q > 0)$. Also, if both $d_p$ and $d_q$ are zero, then there are no binaries in either child of binary $k$ with the highest level. In that case, the corresponding terms vanish (see below).

When rewriting the summations $u_1, ..., u_n \in \mathcal{B}$ to summations over both children of binary $k$, it should be taken into account that for given $n_1, n_2, d_p, d_{p_1}, ..., d_{p_{n_1 - d_p}}, d_q, d_{q_1}, ..., d_{q_{n_2 - d_q}},$ there are multiple possible permutations of the binaries $p, p_1, ..., p_{n_1 - d_p}, q, ..., q_{n_2 - d_q}$ from the set $u_1, ..., u_n \in \mathcal{B}$. The number of permutations is determined by $n$ and the number of recurrences of each of the binaries. This is equivalent to placing numbers in $n$ slots, where there are $d_p$ identical numbers, $d_{p_1}$ other identical numbers, $d_{p_2}$ other identical numbers, etc.
This gives a number of permutations
\[ \mathcal{P}_{d_1, n_2}^{d_1, n_2} \equiv \mathcal{P}_{d_1, d_2}^{d_1, d_2} = \frac{1}{(n_1 + n_2)!} \prod_{i=1}^{n_1+n_2} (d_1^i)!(d_2^i)! \quad (A89) \]
where \( \mathcal{P}_{d_1, d_2}^{d_1, d_2} \) is short-hand notation, and \( n_2 = n - n_1 \). Note that the quantity \( \beta_0(\mathbf{r}_{a_1}, \ldots, \mathbf{r}_{a_n}, \mathbf{r}_k) \) is invariant under each permutation because it does not depend on the order of any of the first \( n \) arguments (cf. Appendix A2). Evidently, the same applies to the scalar multiplication \( B_{j_1,j_2} \ldots B_{j_{n_1,n_2}} \) in equation (A88).

We thus arrive at the following rewriting of summations,
\[
\sum_{\mathbf{r}_a, \mathbf{r}_b, \mathbf{r}_k \in \mathbb{B}} c_n \beta_0(\mathbf{r}_{a_1}, \ldots, \mathbf{r}_{a_n}, \mathbf{r}_k) \sum_{i \in \{p,C\}} \sum_{j \in \{k,C\}} \alpha(i, j; k)^n m_i m_j B_{i_1,j_2} \ldots B_{i_{n_1},j_{n_2}} \quad (A90)
\]
Note that if \( d_p = 0 (d_q = 0) \), then also the associated recurrences \( d_{p_1}, \ldots, d_{p_1 - d_p} \), \( d_{q_1}, \ldots, d_{q_2 - d_q} \) are zero, and the corresponding product \( B_{i_1,j_2} \ldots B_{i_{p_1},j_{q_2}} \) is unity. The factor \( f(n_1, n_2, d_p, d_q) \) takes into account that the terms corresponding to \( d_p = d_q = 0 \) are zero (see below), and that terms with \( d_p = 0 \) and \( n_1 - d_p > 0 \), and \( d_q = 0 \) and \( n_2 - d_q > 0 \), should be discarded (by definition of the \( p \) and \( q \) binaries). Therefore,
\[
f(n_1, n_2, d_p, d_q) = \begin{cases} 0, & d_p = 0 \text{ and } d_q = 0; \\ 0, & d_p = 0 \text{ and } n_1 - d_p > 0; \\ 0, & d_q = 0 \text{ and } n_2 - d_q > 0; \\ 1, & \text{otherwise.} \end{cases} \quad (A91)
\]
Note that the use of \( f(n_1, n_2, d_p, d_q) \) can be avoided by separating out the terms corresponding to \( d_p = 0 \) and/or \( d_q = 0 \). We nevertheless include it, in order to keep the notation relatively compact.

When summing over body \( i \in \{p,C\}, B_{i,j} = 0 \) for any \( p \) within the binaries \( p_1, \ldots, p_{d_p - d_p} \), unless \( i \in \{p,C\} \) and \( p \in \{p,C\} \). Similarly, \( B_{i,j} = 0 \) for any \( q \) within the binaries \( q_1, \ldots, q_{d_q - d_q} \), unless \( j \in \{q,C\} \) and \( q \in \{q,C\} \). Furthermore, any of the mass ratio quantities \( B_{i_1,j_{p_1}} \ldots B_{i_{d_p},j_{q_2-1}} \) which are non-zero if \( i \in \{p,C\} \) are constant when summing over \( i \in \{p,C\} \) because \( p \) is the highest level binary in child 1 of binary \( k \). Also, for \( i \in \{p,C\} \), the quantities \( B_{i,j} \), \( B_{i_1,j_{d_q-1}} \) are constant because the \( q \)-binaries are, by definition, part of child 2 of binary \( k \), whereas \( p \in \{p,C\} \). Similarly, \( B_{i_{d_p-1},j} \), \( B_{i_{d_q-2},j} \) and \( B_{i,j} \) are constant when summing over body \( j \in \{q,C\} \). Note that when summing \( i \in \{p,C\} \) and \( j \in \{q,C\} \), \( \alpha(i, j; k) = \alpha(p, q; k) \).

Therefore, the summations over bodies \( i \) and \( j \) in equation (A90) can be written as
\[
\sum_{i \in \{p,C\}} \sum_{j \in \{q,C\}} \alpha(i, j; k)^n m_i m_j \left( B_{i,j}^{d_p} B_{i_1,j_{d_q-2}}^{d_q} \right) \left( B_{i,j}^{d_q} B_{i_{d_p},j_{q_2-1}}^{d_q} \right) = \sum_{i \in \{p,C\}} \sum_{j \in \{q,C\}} \alpha(p, q; k)^n m_i m_j \left( B_{i,j}^{d_p} B_{i_1,j_{d_q-2}}^{d_q} \right) \left( B_{i,j}^{d_q} B_{i_{d_p},j_{q_2-1}}^{d_q} \right) = \alpha(p, q; k)^n \left( B_{i,j}^{d_p} B_{i_{d_q-2},j}^{d_q} \right) \left( B_{i,j}^{d_q} B_{i_{d_p-1},j}^{d_q} \right) \quad (A92)
\]
Note that the mass ratio factors outside of the summations of \( i \) and \( j \) are in fact independent of \( i \) and \( j \). One could e.g. write \( B_{i,j} = B_{pq}. \)

Similarly to the previous appendices, the expressions in equation (A92) with remaining summations over bodies can be simplified by summing separately over the two children of \( p \) and \( q \), and by substituting the explicit expression for the mass ratio quantities. For binary \( p \),
\[
\sum_{i \in \{p,C\}} m_i B_{i,j}^{d_p} = \left( \sum_{i \in \{p,C\}} m_i B_{i,j}^{d_p} \right) \left( \alpha(p.C1, k.CS(p); p) M_{p,C1} \right) = \alpha(p.C1, k.CS(p); p) M_{p,C1} \quad (A93)
\]
Finally, we normalize \( M_{p,C1} \) to be \( \sum_{i \in \{p,C\}} m_i = 1 \).

\[M_{p,C1} = \sum_{i \in \{p,C\}} m_i = 1 \quad \rightarrow \quad \alpha(p.C1, k.CS(p); p) = \frac{1}{M_{p,C1}} \quad (A93)
\]
where, for convenience, we introduced the short-hand notation $\mathcal{N}_{d,p,C}(p)$. Analogously,

$$
\sum_{j \in \{p,C\}} m_j B_{ijq}^{d,p} = \mathcal{N}_{d,p,C}(q). \quad (A94)
$$

Note that equation (A93) is essentially a generalized version of the quantity ‘$M_j$’ that appears at order $j$ in the hierarchical three-body problem as given by equation (1) of Harrington (1968) – in the latter paper, $M_j$ is multiplied by the tertiary mass ‘$m_3$’; in our case, this corresponds to $\mathcal{N}_{d,p,C}(q)$. Special values of $\mathcal{N}_{d,p,C}(p)$ of interest here are

$$
\mathcal{N}_{d,p,C}(s) = \alpha(p,C_1,k,CS(p); p) \frac{M_{p,C_1} M_{p,C_2} M_{p,C_2}^{-1} + M_{p,C_1}^{-1}}{M_p} = M_{p,C_1} + M_{p,C_2} = M_p, \quad (A95)
$$

and

$$
\mathcal{N}_{d,p,C}(s) = \alpha(p,C_1,k,CS(p); p) \frac{M_{p,C_1} M_{p,C_2} M_{p,C_2}^{-1} - M_{p,C_1}^{-1}}{M_p} = 0. \quad (A96)
$$

Substituting explicit expressions for the remaining mass ratio quantities $B_{ijp_1, ..., B_{ijp_1-d_p}$ and $B_{ijq_1, ..., B_{ijq_1-d_q}$, we find the following general expression for the potential energy,

$$
S_{\alpha} = (-1)^{n+1} \sum_{k \in B} \left( \sum_{l=0}^{n_1} \sum_{d_p=0}^{n_2} \sum_{d_q=0}^{n_2} \right) \left( \mathcal{N}_{d,p,C}(s) \mathcal{N}_{d,q,C}(s) \right) \times \alpha(p, q; k) f(n_1, n_2, d_p, d_q) \left[ \prod_{i=1}^{n_1} \left[ \frac{\alpha(p, k, CS(p); k) M_{p,C}(s)}{M_p} \right] \right] \left[ \prod_{i=1}^{n_2} \left[ \frac{\alpha(q, k, CS(q); k) M_{q,C}(s)}{M_q} \right] \right] 
\times \mathcal{N}_{d,p,C}(s) \mathcal{N}_{d,q,C}(s), \quad (A97)
$$

where $f(n_1, n_2, d_p, d_q)$ was defined in equation (A91). Note that the products in curly brackets are to be evaluated up to the unity limit of the variable $l$, i.e. $n_1 - d_p$ or $n_2 - d_q$, is zero (this corresponds to no binaries $p_1$ or $q_1$ such that $p \in \{p,C\}$ or $q \in \{q,C\}$).

Each individual term in equation (A97) depends on binary $k$ and, depending on the values of $d_p$ and $d_q$, binaries $p$ and at most $n_1 - d_p$ distinct binaries $p_1, ..., p_{n_1-d_p}$, and binaries $q$ and at most $n_2 - d_q$ distinct binaries $q_1, ..., q_{n_2-d_q}$. If $d_p \neq 0$ and $d_q \neq 0$, then the number of distinct binaries is at most $N_{\text{bin,dis}} = 1 + (1 + n_1 - d_p) + (1 + n_2 - d_q) = 3 + n - d_p - d_q$. This number is maximized when $d_p$ and $d_q$ are smallest. Because the product $\mathcal{N}_{d,p,C}(p) \mathcal{N}_{d,q,C}(q)$ is zero whenever one or both of $d_p$ and $d_q$ are unity (cf. equation A96), the lowest allowed values of $d_p > 0$ and $d_q > 0$ are $d_p = 2$ and $d_q = 2$, which corresponds to $N_{\text{bin,dis}} = 3 + n - 4 = n - 1$.

However, the case that either $d_p$ or $d_q$ are zero should also be considered. If, e.g., $d_p = 0$ and $d_q \neq 0$, then the occurring binaries are $k$ and at most $n_1 - d_p$ distinct binaries $p_1, ..., p_{n_1-d_p}$. The corresponding number of distinct binaries is $N_{\text{bin,dis}} = 1 + (1 + n_1 - d_p) = 2 + n_1 - d_p$. The maximum $N_{\text{bin,dis}}$ occurs when $n_1 = n_2 = 2$ (again, terms corresponding to $d_p = 1$ vanish due to equation A96), giving $N_{\text{bin,dis}} = 2 + n - 2 = n$. Evidently, the same result applies when choosing $d_p = 0$ and $d_q \neq 0$.

We conclude that the individual terms in the Hamiltonian depend on at most $n$ different binaries. Because ‘single’ terms depending on just one binary are not allowed (in addition to binary $k$, there will always be another binary in either $p$ or $q$ families), the maximum number of types of terms (i.e. binary pairs, triplets, quadruplets, etc.) is $n - 1$.

More than one binary with the highest level in either child of binary $k$. As mentioned above, it is possible that in either child of binary $k$, there is no unique binary with the highest level. In this case, let $v_1, ..., v_l$ denote the $s$ binaries with the common highest level in either of the two children of binary $k$. When summing over $i \in \{k,C\}$, $B_{i jv_i} = 0$ for binary $v_i$ unless $i \in \{v_j,C\}$. However, when summing $i \in \{v_j,C\}$, the other $B_{i jv_j}$ (excluding $B_{j jv_i}$) are zero, because, by definition, the $v$-binaries are on the same level. Therefore, if there is more than one binary with the highest level in either child of binary $k$, then the corresponding terms vanish. This is taken into account in equation (A97) with the factor $f(n_1, n_2, d_p, d_q)$ (cf. equation A91).

Pairwise binary terms. Equation (A97) can be made more explicit for the pairwise binary terms. In that equation, the pairwise binary terms correspond to (1) $n_1 = n (n_2 = 0), d_p = n_1 - n$ and $d_q = 0$, and (2) $n_1 = 0 (n_2 = n), d_p = n_2 = n$ and $d_q = 0$. In these cases, $n_1 - d_p = 0$ and $n_2 - d_q = 0$, and there are no summations of the binaries $p_1, ..., p_{n_1-d_p}$ and $q_1, ..., q_{n_2-d_q}$. Also, in case (1), there is no summation over the
Table A3. Combinations of $n_1$, $n_2$, $d_p$ and $d_q$ occurring in equation (A97) for $n = 3$. For each combination, we note whether or not it is included in the summations.

</table>

$q$-binaries; in case (2), there is no summation over the $p$-binaries. Furthermore, the number of permutations is $P(n_1, n_2, d_p, d_q) = n! / n! = 1$, and the products in the curly brackets evaluate to unity. The resulting expression is

$$
S_{n_2} = (-1)^{n_1 + 1} \sum_{k \in B} \frac{G}{r_k} \left[ \sum_{p \in B} \frac{c_p \beta_p(r_p, \ldots, r_p)}{p} M_{p,1}^{(d_1)} M_{p,2}^{(d_2)} M_{q,1}^{(d_1)} M_{q,2}^{(d_2)} \right] + \sum_{q \in B} c_q \beta_q(r_q, \ldots, r_q) \sum_{p \in B} M_{p,1}^{(d_1)} M_{p,2}^{(d_2)} M_{q,1}^{(d_1)} M_{q,2}^{(d_2)} \tag{A98}
$$

where in the second line, we changed the variable $q$ in the second term to $p$, and combined the two separate summations over child 1 and child 2 of $k$ into one summation over all children. Note that $M_{p,1}^{(d_1)} M_{p,2}^{(d_2)} M_{q,1}^{(d_1)} M_{q,2}^{(d_2)}$ simply evaluates to $M_{L,CS(p),p}$ (cf. equation A95). This gives

$$
S_{n_2} = (-1)^{n_1 + 1} \sum_{k \in B} \frac{M_{p,1}^{(d_1)} M_{p,2}^{(d_2)}}{p} \alpha(p, C_1, k, C_2; p) \sum_{p \in B} M_{p,2}^{(d_2)} \sum_{p \in B} \frac{G M_{L,CS(p)}}{r_k} c_p \beta_p(r_p, \ldots, r_p, r_k) \tag{A99}
$$

In the second line, we used equation (A30) (recall that the $A_{m,n}^{(d)}$ are integer ratio coefficients, which are the same coefficients appearing in the $n$th Legendre polynomials, cf. equations A30 and A31).

Demonstration of equation (A97). As a demonstration, we apply equation (A97) to the case $n = 3$ (octupole order), and show that the resulting expression is the same as the expression that was previously derived in Appendix A4.4. For $n = 3$, the combinations of $n_1$, $n_2$, $d_p$ and $d_q$ are enumerated in Table A3. For each combination, we note whether or not it occurs in the summation, either because of the properties of the
quantity \( f(n, m, d_p, d_q) \) (cf. equation A91) or because of property equation (A96). For the triplet terms, note that \( T_{d_p,d_q}^{n,m} = 3!/2! = 3 \). This gives

\[
S_3 = \sum_{k,B} \sum_{q,B} \sum_{q,C} G \frac{C_3 (r_p, r_q, r_p, r_q, r_k)}{r_k} \times 1 \times \alpha(q, k, CS(q); k) M_{k,CS(q)} \frac{M_{q,1} M_{q,2} M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, q, C_1, k, CS(q); q) \frac{M_{q,1} M_{q,2} - M_{q,1} M_{q,2}}{M_q} \\
+ \sum_{k,B} \sum_{p,B} \sum_{q,C} G \frac{C_3 (r_p, r_p, r_p, r_q, r_k)}{r_k} \times 1 \times \alpha(p, k, CS(p); p) M_{k,CS(p)} \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, q, C_1, k, CS(p); p) \frac{M_{p,1} M_{p,2} - M_{p,1} M_{p,2}}{M_p} \\
+ \sum_{k,B} \sum_{q,B} \sum_{q,C} G \frac{C_3 (r_p, r_q, r_q, r_q, r_k)}{r_k} \times 1 \times \alpha(q, k, CS(q); k) M_{k,CS(q)} \frac{M_{q,1} M_{q,2} M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, q, C_1, k, CS(p); q) \frac{M_{q,1} M_{q,2} - M_{q,1} M_{q,2}}{M_q}
\]

Taking together the summations over \( p \) and \( q \) into a single summation of \( p \) over both children of \( k \) for the binary pair and triplet terms, relabelling \( q_1 = u \) and \( p_1 = u \) and substituting the expressions for \( c_3 \beta_3 \), we recover equation (A76).

### A4.8 Summary

In the previous appendices, we explicitly carried out the rewriting procedure for all terms up and including octupole order, and including the binary pair terms at hexadecupole and dotriacontupole order. We also derived a general, more implicit expression valid for any order \( n \) and including all binary interactions (cf. Appendix A4.7). For the purposes of giving a useful overview, we repeat the explicit expressions here. The simplified explicit expression reads

\[
H = \frac{1}{2} \sum_{k,B} \left[ \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} (\hat{r}_p \cdot \hat{r}_k) - \frac{G M_{p,1} M_{p,2} M_{p,3}}{r_k} \alpha(p, C_1, k, CS(p); p) \frac{M_{p,1} C_1 M_{p,2} C_2}{M_p} \alpha(p, k, CS(p); k) \frac{M_{p,1} C_1 M_{p,2} C_2}{M_p} \right] + S'_2 + S'_3 + S'_4 + S'_5 + \cdots
\]  

(A101)

where

\[
S'_2 = -\frac{1}{2} \sum_{k,B} \sum_{p,B} \sum_{q,C} G \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, C_1, k, CS(p); p) \frac{M_{p,1} C_1 M_{p,2} C_2}{M_p} \alpha(p, k, CS(p); k) \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \left( \frac{r_p}{r_k} \right)^2 \left[ 3(\hat{r}_p \cdot \hat{r}_k)^2 - 1 \right] ;
\]  

(A102)

\[
S'_3 = \frac{1}{2} \sum_{k,B} \sum_{p,B} \sum_{q,C} G \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, C_1, k, CS(p); p) \frac{M_{p,1} C_1 M_{p,2} C_2}{M_p} \alpha(p, k, CS(p); k) \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \left( \frac{r_p}{r_k} \right)^3 \left[ 5(\hat{r}_p \cdot \hat{r}_k)^3 - 3(\hat{r}_p \cdot \hat{r}_k)^3 \right]
\]

(A103)

\[
S'_4 = -\frac{3}{2} \sum_{k,B} \sum_{p,B} \sum_{q,C} \sum_{u,C} \sum_{v,C} \alpha(p, C_1, k, CS(p); p) \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, k, CS(p); k) \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, u, CS(p); u) \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \left( \frac{r_p}{r_k} \right)^2 \left( \frac{r_u}{r_k} \right) \times \left[ 5(\hat{r}_p \cdot \hat{r}_k)^2 (\hat{r}_u \cdot \hat{r}_k) - 2(\hat{r}_p \cdot \hat{r}_u) (\hat{r}_p \cdot \hat{r}_k) - (\hat{r}_u \cdot \hat{r}_k) \right] ;
\]  

(A104)

\[
S'_5 = -\frac{1}{8} \sum_{k,B} \sum_{p,B} \sum_{q,C} \alpha(p, C_1, p, CS(p); p) \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, C_1, p, CS(p); p) \frac{M_{p,1} C_1 M_{p,2} C_2 + M_{p,1} C_2 M_{p,2} C_1}{M_p} \frac{M_{p,1} C_1 M_{p,2} C_2}{M_p} \left( \frac{r_p}{r_k} \right)^4 \left[ 35(\hat{r}_p \cdot \hat{r}_k)^4 - 30(\hat{r}_p \cdot \hat{r}_k)^4 + 3 \right] + S'_{4,3} + S'_{4,4} ;
\]

(A105)

\[
S'_3 = \frac{1}{8} \sum_{k,B} \sum_{p,B} \sum_{q,C} \alpha(p, C_1, p, CS(p); p) \frac{M_{p,1} M_{p,2} M_{p,3}}{M_p} \alpha(p, C_1, p, CS(p); p) \frac{M_{p,1} C_1 M_{p,2} C_2 + M_{p,1} C_2 M_{p,2} C_1}{M_p} \frac{M_{p,1} C_1 M_{p,2} C_2}{M_p} \left( \frac{r_p}{r_k} \right)^5 \times \left[ 63(\hat{r}_p \cdot \hat{r}_k)^5 - 70(\hat{r}_p \cdot \hat{r}_k)^5 + 15(\hat{r}_p \cdot \hat{r}_k)^5 \right] + S'_{4,3} + S'_{4,4} + S'_{5,5} ;
\]

(A106)

Here, the dots in equation (A101) denote higher order terms. Note that in equation (A101), no approximations are made apart from the expansions in the binary separation ratios. Below, in Appendix A5, we orbit average equation (A101).
A5 Orbit averaging

We average the expanded Hamiltonian over the $N - 1$ binary orbits, assuming that in each orbit, the motion on suborbital time-scales can be well approximated by a bound Kepler orbit. We define the orbit-averaged Hamiltonian as

$$H = \frac{1}{(2\pi)^{N-1}} \int_0^{2\pi} \cdots \int_0^{2\pi} H d\ell_k,$$  \hspace{1cm} (A107)

where $\ell_k$ is the mean anomaly of orbit $k$. We express the angular momenta and orientations of each binary in terms of the triad of perpendicular orbital state vectors $(j_k, e_k, q_k)$, where $q_k = j_k \times e_k$. Here, $j_k$ is the specific angular momentum vector with magnitude $j_k = \sqrt{1 - e_k^2}$, where $e_k, 0 \leq e_k < 1$, is the orbital eccentricity. The specific orbital angular momentum vector $j_k$ is related to the orbital angular momentum $u_k = M_k e_k \hat{a}_k$ with a high negative power, $M_k = M_{\text{C1}} M_{\text{C2}} / M_k$ (A108)

$$\Lambda_k = M_{\text{C1}} M_{\text{C2}} \sqrt{\frac{G \mu_k}{M_k}},$$

with $a_k$ the semimajor axis. Furthermore, $e_k$ is the eccentricity or Laplace–Runge–Lenz vector that is aligned with the major axis and that has magnitude $e_k$.

In terms of $e_k$ and $q_k$, and the orbital phase (we use either the true anomaly $f_k$ or the eccentric anomaly $\varepsilon_k$ as integration variables), the dot product of $r_k$ with some other (constant) vector $u$ is given by two equivalent expressions,

$$r_k \cdot u = \frac{a_k}{1 + e_k \cos(f_k)} \cos(f_k) (\hat{e}_k \cdot u) + \sin(f_k) (\hat{q}_k \cdot u) = a_k \left[ \cos(\varepsilon_k) - e_k \right] (\hat{e}_k \cdot u) + a_k \sqrt{1 - e_k^2} \sin(\varepsilon_k) (\hat{q}_k \cdot u).$$  \hspace{1cm} (A109)

The simplified Hamiltonian, equation (A101), is expressed in terms of these dot products. Furthermore, the separations are given by the well-known expressions

$$r_k = \frac{a_k}{1 + e_k \cos(f_k)} = a_k [1 - e_k \cos(\varepsilon_k)].$$  \hspace{1cm} (A110)

In equation (A107), it is convenient to use the true anomaly $f_k$ as the integration variable whenever $r_k$ appears with a high negative power, and, otherwise, the eccentric anomaly $\varepsilon_k$. The relevant Jacobians are given by

$$d\ell_k = \frac{1}{\sqrt{1 - e_k^2}} \left( \frac{r_k}{a_k} \right)^2 d\varepsilon_k = \left( \frac{r_k}{a_k} \right) d\varepsilon_k.$$  \hspace{1cm} (A111)

In order to express the orbit-averaged quantities in terms of dot products of $e_k$ and $j_k$ with those of other orbits (i.e. to remove any reference to the auxiliary vector $q_k$), we repeatedly use the following vector identity for the scalar product of two scalar triple products,

$$(\hat{q}_k \cdot u)(\hat{q}_k \cdot w) = [(\hat{j}_k \times \hat{e}_k) \cdot u][(\hat{j}_k \times \hat{e}_k) \cdot w] = u \cdot w - (\hat{e}_k \cdot u)(\hat{e}_k \cdot w) - (\hat{j}_k \cdot u)(\hat{j}_k \cdot w),$$  \hspace{1cm} (A112)

where $u$ and $w$ are two arbitrary vectors.

For example, the orbit average of the term $\langle (r_p \cdot r_k)^2 / r_k^5 \rangle$ that appears in the quadrupole-order term of the Hamiltonian (cf. equation A101) is given by

$$\langle (r_p \cdot r_k)^2 / r_k^5 \rangle_p = \frac{a_p^2}{2r_k^2} \left[ j_k^2 r_k^2 - (j_p \cdot r_k)^2 + 5(e_p \cdot r_k)^2 \right];$$  \hspace{1cm} (113a)

$$\langle (r_p \cdot r_k)^2 / r_k^5 \rangle_p = \frac{a_p^2}{4a_k^2 j_k} \left[ (1 + 4e_p^2) j_k^2 + (j_p \cdot j_k)^2 - 5(e_p \cdot j_k)^2 \right].$$  \hspace{1cm} (113b)

Note that this expression is well defined in the limit $e_p \to 0$, in which case $e_p \to 0$.

Formally, the averaging of the Hamiltonian over the binary orbits as described by equation (A107) is not a canonical transformation. However, applying the Von Zeipel transformation technique to the unaveraged Hamiltonian (Brouwer 1959), a canonical transformation can be found that eliminates the short-period terms $l_k$ from the Hamiltonian (cf. appendix A2 of Naoz et al. 2013a; the derivation presented there is straightforwardly extended to $N - 1$, rather than two short-period variables). This transformation leads to a transformed Hamiltonian that is equivalent to equation (A107). The transformed coordinates $e^*_k$ and $q^*_k$ differ from the original ones, $e_k$ and $q_k$. However, as noted by Naoz et al. (2013a), the untransformed and the transformed coordinates differ by order $x^2$. Therefore, this difference can usually be neglected. This is borne out by our tests with other methods (cf. Section 3).

\subsection*{A5.1 Binding energies}

If Kepler orbits are assumed, the first two summation terms in equation (A101) immediately reduce to the sum of the binary binding energies, without having to explicitly average over the orbits. This directly follows from the canonical expressions for the Kepler binary separation
(equation A110) and the squared velocity,
\[
\dot{r}_k \cdot \dot{r}_k = \frac{GM_k}{a_k \left(1 - e_k^2\right)} \left[1 + 2e_k \cos(f_k) + e_k^2\right].
\]  
(A114)

Substituting these expressions into the term in equation (A101) with the single summation of \(k \in B\), we find
\[
\sum_{k \in B} \left[\frac{1}{2} \frac{M_k}{M_2} (\dot{r}_k \cdot \dot{r}_k) - \frac{GM_k}{r_k^3} \right] = \sum_{k \in B} \frac{GM_k}{r_k^3} = \sum_{k \in B} \frac{GM_{k1}M_{k2}}{-2a_k}.
\]
(A115)

Each of the individual terms in the latter expression is the Keplerian binary binding energy \(E_k < 0\). Because they only depend on the semimajor axes (and not on \(e_k\) and \(j_k\)), equation (A115) does not give rise to secular changes of the orbits (cf. equations 17).

A5.2 Higher order terms

Secular changes arise from the higher order orbit-averaged terms \(S_n\) with \(n \geq 2\), which depend on \(e_k\) and \(j_k\). These terms combined form the disturbing function of the system. Given their mathematical equivalence to the corresponding terms in the hierarchical three-body problem, orbit-averaged expressions for the binary pair terms in the Hamiltonian up and including octupole order can be directly taken from previous studies (e.g. Boué & Fabrycky 2014, where the same vector formalism was adopted). The orbit-averaged octupole-order term depending on three binaries and the hexadecapole-order term depending on two binaries were derived previously by Hamers et al. (2015). In the latter work, these terms were expressed in terms of unit vectors \(\hat{e}_k\), which are ill-defined in the limit \(e_k \to 0\). Here, we have rederived the orbit average of all terms up and including dotriacontapole order as given explicitly in equation (A101), where for the hexadecapole- and dotriacontapole-order terms, we only included the binary pair terms. We have expressed the result in terms of the non-unit vectors \(e_k\), which are well defined in the limit \(e_k \to 0\), i.e. trivially, \(e_k \to 0\). We have verified the expressions of Hamers et al. (2015) numerically for cases with non-zero eccentricities.

After averaging over the orbits, the Hamiltonian is no longer a function of the phases of the orbits \(l_i\). Consequently, the sign quantities \(\alpha\) must be set to unity. A subtlety arises with the binary pair octupole- and dotriacontapole-order terms (or, generally odd order \(n\)), which contain the factor
\[
\alpha(p.C1, k.CS(p); p)(M_{p,C2} - M_{p,C1}) = \alpha(p.C2, k.CS(p); p)(M_{p,C1} - M_{p,C2}).
\]  
(A116)

After averaging, interchanging the children of \(p\) should not change the expression. Therefore, the expression equation (A117) should be replaced by the absolute mass difference, i.e.
\[
\alpha(p.C1, k.CS(p); p)(M_{p,C2} - M_{p,C1}) \to |M_{p,C1} - M_{p,C2}|.
\]  
(A117)

The explicit orbit-averaged Hamiltonian, to dotriacontapole order, reads
\[
\mathcal{H} = \sum_{k \in B} \left(\frac{GM_{k1}M_{k2}}{-2a_k}\right) + \mathcal{S}_2 + \mathcal{S}_3 + \mathcal{S}_4 + \mathcal{S}_5 + \ldots.
\]

where

\[
\mathcal{S}_2 = \sum_{k \in B} \sum_{p \in B} \sum_{p \in B} \frac{M_{p1}M_{p2}C1M_{p2}C1}{M_p} \frac{M_{k1}CS(p)}{a_k} \left(\frac{a_p}{a_k}\right)^2 \frac{1}{8j_k^3} \left[5(1 - 6e_p^2)j_k^2 + 15(e_p \cdot j_k)^2 - 3(j_p \cdot j_k)\right];
\]  
(A118)

\[
\mathcal{S}_3 = \sum_{k \in B} \sum_{p \in B} \sum_{p \in B} \frac{M_{p1}M_{p2}C1M_{p2}C1}{M_p} \frac{M_{k1}CS(p)}{a_k} \left(\frac{a_p}{a_k}\right)^3 \frac{15}{64j_k^3} \left[10(e_p \cdot j_k)(e_p \cdot j_k)(j_p \cdot j_k)\right]
\]

\[
- (e_p \cdot e_k) \left[5(1 - 8e_p^2)j_k^2 + 35(e_p \cdot j_k)^2 - 5(j_p \cdot j_k)\right] \}
\]

\[
+ \sum_{k \in B} \sum_{p \in B} \sum_{p \in B} \sum_{p \in B} \frac{M_{p1}M_{p2}C1M_{p2}C1}{M_p} \frac{M_{k1}CS(p)}{a_k} \left(\frac{a_p}{a_k}\right)^2 \left(\frac{a_p}{a_k}\right) \left(\frac{a_p}{a_k}\right) \frac{9}{32j_k^3} \left[10(e_p \cdot e_k)(e_p \cdot e_k)(j_p \cdot j_k)\right]
\]

\[
- 50(e_p \cdot e_k)(e_p \cdot j_k)(e_p \cdot j_k) - 2(e_p \cdot j_k)(e_p \cdot j_k)d_k^2 + 10(e_p \cdot j_k)(e_p \cdot j_k)(j_p \cdot j_k)\]

\[
- (e_p \cdot e_k) \left[5(1 - 6e_p^2)j_k^2 + 25(e_p \cdot j_k)^2 - 5(j_p \cdot j_k)\right];
\]  
(A119)
\[ S_k = \sum_{k \in B} \sum_{p \in B} M_{p,C1} M_{p,C2} M_{p,C1}^2 M_{p,C2}^2 G M_{LCS(p)} \left( \frac{a_p}{a_k} \right)^4 \frac{3}{1024 j_k^{11}} \left\{ 3 j_k^1 \left[ -6 + e_i^2 + 40 e_p^2 (1 + 8 e_k^2) \right] \cdot e_j^2 \cdot \epsilon \right\} \]

\[ \cdot 2 e_z^2 \cdot \epsilon \left[ -2 (2 + e_i^2) j_k^2 + 21 (e_p \cdot j_k) \right] \]

\[ - 5880 j_k^2 (e_p \cdot e_k) (e_p \cdot j_k) (e_p \cdot j_k) (j_p \cdot j_k) \]

\[ + 5 \left[ 28 j_k^2 \left( 1 - 10 e_i^2 \right) \left( 4 + 3 e_i^2 \right) (e_p \cdot j_k)^2 - 6 j_k^2 (8 + 6 e_i^2 + e_p^2 (6 + 29 e_i^2)) (j_p \cdot j_k)^2 - 12 j_k^2 (e_p \cdot j_k)^2 \right] \left( (1 + 13 e_i^2) j_k^2 - 7 (j_p \cdot j_k)^2 \right) \]

\[ + 98 j_k^2 \left( -2 - 3 e_i^2 + 4 e_p^2 (5 + 3 e_i^2) \right) (e_p \cdot j_k)^2 - 441 (2 + e_i^2) (e_p \cdot j_k)^2 + 42 (2 + e_i^2) (j_p \cdot j_k)^2 + 7 (e_p \cdot j_k)^2 (j_p \cdot j_k)^2 \]

\[ - 21 (2 + e_i^2) (j_p \cdot j_k)^2 \] \(+ \mathcal{S}_{4,3} + \mathcal{S}_{4,4} \); \( \mathcal{A}_{120} \)

\[ S_5 = \sum_{k \in B} \sum_{p \in B} M_{p,C1} M_{p,C2} |M_{p,C1}| M_{p,C2}^2 G M_{LCS(p)} \left( \frac{a_p}{a_k} \right)^6 \frac{105}{4096 j_k^{11}} \left\{ 3024 (e_p \cdot e_k)^2 (e_p \cdot j_k) (e_p \cdot j_k) (j_p \cdot j_k) \right\} \]

\[ - 28 j_k^2 (e_p \cdot e_k)^3 \left[ \left( -26 + 15 e_i^2 \right) j_k^2 + 18 (j_p \cdot j_k)^2 + 99 (e_p \cdot j_k)^2 \right] - 28 (e_p \cdot j_k) (e_k \cdot j_p) (j_p \cdot j_k) \left[ (1 - 4 e_i^2) \left( 8 + e_i^2 \right) j_k^2 \right] \]

\[ + 9 \left( 8 + 3 e_i^2 \right) (e_p \cdot j_k)^2 + 6 j_k^2 (e_p \cdot j_k)^2 - 3 \left( 8 + 3 e_i^2 \right) (j_p \cdot j_k)^2 - (e_p \cdot e_k) \left[ \left( -8 + e_i^2 + e_p^2 \left( 64 + 748 e_i^2 \right) - 4 e_p^2 \left( 80 + 179 e_i^2 \right) \right) j_k^2 \right] \]

\[ - 693 (8 + 3 e_i^2) (e_p \cdot j_k)^2 + 42 (e_p \cdot j_k)^2 \left[ \left( -8 - 19 e_i^2 + 6 e_p^2 \left( 16 + 5 e_i^2 \right) \right) j_k^2 + 9 \left( 8 + 3 e_i^2 \right) (j_p \cdot j_k)^2 \right] \]

\[ + 14 j_k^2 \left( 8 + e_i^2 - 2 e_p^2 \left( 16 + 29 e_i^2 \right) \right) (j_p \cdot j_k)^2 - 21 (8 + 3 e_i^2) (j_p \cdot j_k)^2 - 28 (e_k \cdot j_p)^2 j_k^2 - 28 (e_p \cdot j_p)^2 j_k^2 \]

\[ \left( (1 + 23 e_p^2) j_k^2 - 9 (j_p \cdot j_k)^2 \right) \] \(+ \mathcal{S}_{5,3} + \mathcal{S}_{5,4} + \mathcal{S}_{5,5} \); \( \mathcal{A}_{121} \)

A5.3 General formal expressions for the orbit-averaged binary pair terms at order \( n \)

For the binary pair terms, we show how the orbit-averaged integrals at any order can be evaluated using complex integration techniques. We note that Mandling (2013) derived the equivalent orbit-averaged terms for hierarchical three-body systems in terms of Hansen coefficients which are also valid for arbitrary order, but assuming coplanar orbits.

From equation (A99), the terms depending on binary separations in the unaveraged binary pair Hamiltonian at order \( n \) are given by

\[ \sum_{m=0}^{n} \frac{(r_p \cdot r_k)^m r_p^{n-m}}{r_p^{n+1+m}} A_{(m)} \]

where binary \( p \in \{ k, C \} \) (i.e. \( r_p \ll r_k \)), and \( A_{(m)} \) are coefficients that follow from the Taylor expansion of the potential energy and which are the same as the coefficients appearing in the Legendre polynomials (cf. Appendix A2, in particular equations A30 and A31). Generally, \( A_{(0)} = 0 \) if \( n \) is even and \( m \) is odd, or if \( n \) is odd and \( m \) is even.

We first average over the ‘inner’ orbit \( r_p \) with constant \( r_k \) using the eccentric anomaly \( e_p \), giving (cf. equations A107, A109, A110 and A111)

\[ \langle (r_p \cdot r_k)^m r_p^{n-m} \rangle_p = \frac{a_p}{2\pi} \int_0^{2\pi} d\epsilon_p \left[ 1 - e_p \cos(\epsilon_p) \right]^{n-m+1} \left[ \cos(\epsilon_p) - e_p (\hat{e}_p \cdot r_k) + \sqrt{1 - e_p^2 \sin(\epsilon_p) (\hat{q}_p \cdot r_k)^2} \right]^m \]

Subsequently, we transform to the complex variable \( z = \exp(i\epsilon_p) \) where \( i = \sqrt{-1} \), giving

\[ \langle (r_p \cdot r_k)^m r_p^{n-m} \rangle_p = \frac{a_p}{2\pi} \int \frac{dz}{i\pi} \left[ 1 - \frac{e_p}{2} (z + z^{-1}) \right]^{n-m+1} \left[ \sqrt{2} \left( z + z^{-1} - 2 e_p (\hat{e}_p \cdot r_k) - \sqrt{1 - e_p^2 (z - z^{-1}) (\hat{q}_p \cdot r_k)^2} \right)^m \right] \]

\[ \left[ \frac{\bar{C}_1}{e_p} z^2 + \bar{C}_2 z + \bar{C}_3 \right]^{m} \]

Here, the integration path \( C \) is the unit circle \( z = \exp(i\epsilon_p), \epsilon_p \in [0, 2\pi) \) in the complex plane, and the constants \( \bar{C}_1, \bar{C}_2 \) and \( \bar{C}_3 \) are defined by

\[ \bar{C}_1 \equiv (e_p \cdot r_k) - i \sqrt{1 - e_p^2} e_p (\hat{q}_p \cdot r_k) = (e_p \cdot r_k) - i \sqrt{1 - e_p^2} (\pm 1) \left[ e_p^2 r_k^2 - (e_p \cdot r_k)^2 - \frac{e_p^2}{1 - e_p^2} (j_p \cdot r_k)^2 \right]^{1/2} \]

\[ \bar{C}_2 \equiv (e_p \cdot r_k) + i \sqrt{1 - e_p^2} e_p (\hat{q}_p \cdot r_k) = (e_p \cdot r_k) + i \sqrt{1 - e_p^2} (\pm 1) \left[ e_p^2 r_k^2 - (e_p \cdot r_k)^2 - \frac{e_p^2}{1 - e_p^2} (j_p \cdot r_k)^2 \right]^{1/2} \]
\[ \tilde{C}_1 = -2(e_p \cdot r_k), \]  

(125c)

where we used the vector identity equation (A112) to eliminate explicit reference to \( \hat{q}_k \).

Taking into account that \( 0 \leq m \leq n \) and \( n > 0 \), the integrand in equation (A124) is a meromorphic function of \( z \) with a single pole at \( z = 0 \). Using a standard Taylor series, the integrand can be written as

\[ \frac{1}{z^{n+2}} \left( -e_p z^2 + 2z - e_p \right)^{m_n+1} \left( \frac{\tilde{C}_1}{e_p} z^2 + \frac{\tilde{C}_2}{e_p} \right) = \frac{1}{z^{n+2}} \sum_{j=0}^{m} a_j z^j = \sum_{j=0}^{m} a_j \frac{1}{z^{n+2-j}}, \]

(A126)

where the coefficients \( a_j \) are given by

\[ a_j = \frac{1}{j!} \frac{d^j}{dz^j} \left[ (-e_p z^2 + 2z - e_p)^{n-m+1} \left( \frac{\tilde{C}_1}{e_p} z^2 + \frac{\tilde{C}_2}{e_p} \right) \right]_{z=0}^m. \]

(A127)

Using Cauchy's theorem,

\[ \oint_C \frac{dz}{z^k} = \begin{cases} 0, & k \neq 1; \\ 2\pi i, & k = 1, \end{cases} \]

(A128)

it follows that the integral in equation (A124) is zero, unless \( n + 2 - j = 1 \), or \( j = n + 1 \). Therefore, equation (A124) can be written as

\[ \langle (r_p \cdot r_k)^m r_k^{n-m} \rangle_p = a_p \sum_{k_{\text{even}}} \left( 1 - e_p^2 \right) \left[ \tilde{C}_1 \tilde{C}_2 (e_p \cdot r_k)^2 + \left( 1 - e_p^2 \right) \left( e_p^2 - (e_p \cdot r_k)^2 - \frac{e_p^2}{1 - e_p^2} (f_p \cdot r_k)^2 \right) \right]. \]

(A130)

Furthermore, on dimensional grounds, the maximum combined exponent of \( r_k, e_p \cdot r_k \) and \( f_p \cdot r_k \) is \( m \). Therefore, equation (A129) can be formally written as

\[ \langle (r_p \cdot r_k)^m r_k^{n-m} \rangle_p = a_p \sum_{k_{\text{even}}} e_{k_{\text{even}}}^{m+i-1} (1 - e_k^2)^i \left( f_p \cdot r_k \right)^{i_1} \left( f_p \cdot r_k \right)^{i_2} B_{i_1;i_2}^{m}(e_p), \]

(A131)

where \( \mathbb{N}^0 \) are the natural numbers plus zero, and \( B_{i_1;i_2}^{m}(e_p) \) are polynomial functions of \( e_p \) which can be computed from equation (A129).

Subsequently, we average over the 'outer' orbit \( k \) using the true anomaly \( f_k \). From equations (A122) and (A131), it follows that the terms which need to be averaged are of the form (cf. equations A107, A109, A110 and A111)

\[ \left\langle \frac{r_k^{m+i-1} (e_p \cdot r_k)^i (f_p \cdot r_k)^{i_1}}{r_k^{n+i+1}} \right\rangle_k = \left\langle \frac{(e_p \cdot r_k)^i (f_p \cdot r_k)^{i_1}}{r_k^{n+i+1}} \right\rangle_k, \]

(132a)

where we switched again to complex integration with \( z = \exp(i f_k) \), and the constants are given by

\[ \tilde{C}_{1e} = (e_p \cdot b_k) + i e_k (\hat{q}_k \cdot e_p); \]

(133a)

\[ \tilde{C}_{2e} = (e_p \cdot b_k) - i e_k (\hat{q}_k \cdot e_p); \]

(133b)

\[ \tilde{C}_{1j} = (e_k \cdot f_p) + i e_k (\hat{q}_k \cdot f_p); \]

(133c)

\[ \tilde{C}_{2j} = (e_k \cdot f_p) - i e_k (\hat{q}_k \cdot f_p). \]

(133d)
As before, the integrand in equation (A129) is a meromorphic function with a single pole at \( z = 0 \). By the same arguments,

\[
\left\langle \frac{(e_p \cdot r_i)^{j^2}}{r_k^{n+i+j^2+1}} \right\rangle_k = \frac{1}{2} \frac{1}{(n+i+j^2-1)!} \frac{d^{n+i+j^2}}{dz^{n+i+j^2+1}} \left[ \left( e_i z^2 + 2z + e_k \right)^{n-1} \left( \frac{C_{1z} z^2}{e_k} + \frac{C_{1e}}{e_k} \right)^{i_1} \left( \frac{C_{2z} z^2}{e_k} + \frac{C_{1l}}{e_k} \right)^{i_2} \right]_{z=0}.
\]  

(A134)

The expression in equation (A134) is generally a function of \( e_p, e_k, e_p \cdot e_i, j_p \cdot j_k, e_p \cdot j_i, e_k \cdot j_i, e_k \cdot j_k \). The combined exponent of \( e_p \cdot e_i \) and \( e_k \cdot j_k \) is at most \( i_1 \), whereas the combined exponent of \( j_p \cdot j_i \) and \( e_k \cdot j_i \) is at most \( i_2 \). Formally, equation (A134) can be written as

\[
\left\langle \frac{(e_p \cdot r_i)^{j^2}}{r_k^{n+i+j^2+1}} \right\rangle_k = \frac{1}{2} \frac{1}{(n+i+j^2-1)!} \sum_{l_1 \leq l_2 \leq l_1 \leq l_2 \leq l_2} C_{i_1,j_1}(e_p,e_i)(e_p \cdot e_i)^{j_1}(j_p \cdot j_k)^{i_2}(e_p \cdot j_k)^{i_1}(e_k \cdot j_i)^{i_2},
\]  

(A135)

where \( C_{i_1,j_1}(e_p,e_i) \) are polynomial functions of \( e_p \) and \( e_i \) that can be computed from equation (A134) using the vector identity equation (A112).

With these formal expressions for the orbit averages, the averaged pairwise Hamiltonian term to order \( n \) is given by

\[
S_{n,2} = (-1)^{n+1} \sum_{k \in \mathbb{B}} \sum_{p \in \mathbb{C}} \frac{M_{p,C_1} M_{p,C_2} \left| M_{p,C_2} \right|^{n-1}}{M_{p,C_1}} \frac{GM_{p,C_3} \rho_p}{a_k} \frac{1}{j_{k,2}^{2n+1}}
\]

\[
\times \sum_{m=0}^{n} \frac{A_{m} B_{i_1,j_1}^{(n,m)}(e_p,e_i) C_{i_1,j_1}(e_p,e_i)(e_p \cdot e_i)^{j_1}(j_p \cdot j_k)^{i_2}(e_p \cdot j_k)^{i_1}(e_k \cdot j_i)^{i_2},}
\]  

(A136)

where \( A_{m}\) are Legendre polynomial coefficients, given implicitly by (cf. Appendix A2, in particular equations A30 and A31)

\[
\sum_{m=0}^{n} A_{m} x^{m} = \frac{1}{2^{m+n} n!} \frac{d^{m+n}}{dx^{m+n}} \left[ (x^2 - 1)^n \right],
\]  

(A137)

and \( B_{i_1,j_1}^{(n,m)}(e_p,e_i) \) are polynomial functions of \( e_p \) and \( e_i \), given implicitly by

\[
\sum_{l_1 \leq l_2 \leq m} B_{i_1,j_1}^{(n,m)}(e_p,e_i)(e_p \cdot e_i)^{j_1}(j_p \cdot j_k)^{i_2}(e_p \cdot j_k)^{i_1}(e_k \cdot j_i)^{i_2} = \frac{1}{2} \frac{1}{(n+i+j^2-1)!} \frac{d^{n+i+j^2}}{dz^{n+i+j^2+1}} \left[ \left( e_i z^2 + 2z + e_k \right)^{n-1} \left( \frac{C_{1z} z^2}{e_k} + \frac{C_{1e}}{e_k} \right)^{i_1} \left( \frac{C_{2z} z^2}{e_k} + \frac{C_{1l}}{e_k} \right)^{i_2} \right]_{z=0}.
\]  

(A138a)

\[
\sum_{l_1 \leq l_2 \leq l_1 \leq l_2 \leq l_2} C_{i_1,j_1}(e_p,e_i)(e_p \cdot e_i)^{j_1}(j_p \cdot j_k)^{i_2}(e_p \cdot j_k)^{i_1}(e_k \cdot j_i)^{i_2}
\]

\[
= \left( \frac{1}{2} \right)^{n+i+j^2-1} \frac{1}{(n+i+j^2-1)!} \frac{d^{n+i+j^2}}{dz^{n+i+j^2+1}} \left[ \left( e_i z^2 + 2z + e_k \right)^{n-1} \left( \frac{C_{1z} z^2}{e_k} + \frac{C_{1e}}{e_k} \right)^{i_1} \left( \frac{C_{2z} z^2}{e_k} + \frac{C_{1l}}{e_k} \right)^{i_2} \right]_{z=0}.
\]  

(A138b)

Here, the coefficients \( C_{1}, \text{ etc.} \) are given by equations (A125) and (A133).

### A6 Estimate of the importance of non-binary terms for nested planetary systems

Here, we generalize the estimates of the importance of terms other than pairwise binary terms for nested planetary systems, made in Section 2.4.2, to arbitrary order \( n \). As in Section 2.4.2, we consider three nested binaries \( p, u \) and \( k \), where \( p \in \{ k,C \} \), \( p \in \{ u,C \} \) and \( u \in \{ k,C \} \). First, we consider the importance of the pairwise binary terms compared to the triplet term; for the pairwise binary terms, we make a distinction between the pairwise combinations (\( p, u \)) and (\( u, k \)). For our purposes of estimating the (orbit-averaged) Hamiltonian, we approximate \( \beta_k \) as

\[
\beta_k(r_u, \ldots, r_u; r_k) \sim \frac{a_{u_1} \ldots a_{u_n}}{a_k^2},
\]  

(A139)

i.e. we replace the norms of the separation vectors with semimajor axes, and ignore the ‘angular’ dependence, i.e. the dependence on the unit vectors \( r_u \) and \( r_k \) (cf. Appendix A2).
The ratios of the binary triplet to the pairwise term in the Hamiltonian, applied to both pairs \((p, u)\) and \((u, k)\) (cf. equation A144). We assume \(\tilde{q} = 10^{-3}\) and three values of \(\alpha\), indicated in the legend.

Using equation (A97) (or equation A98), this gives the following estimate for the (orbit-averaged) pairwise terms, applied to the pair \((p, u)\),

\[
\mathcal{S}_{n,2}_{(p,u)} \sim \frac{G}{a_u} c_n \left( \frac{a_p}{a_u} \right)^n M_{\text{CS}(p)} M_{p,C1} M_{p,C2} \left| \frac{M_{p,C2}^{n-1} + (-1)^n M_{p,C1}^{n-1}}{M_p^{n-1}} \right|.
\]  

(A140)

Applied to the pair \((u, k)\),

\[
\mathcal{S}_{n,2}_{(u,k)} \sim \frac{G}{a_k} c_n \left( \frac{a_u}{a_k} \right)^n M_{\text{CS}(u)} M_{u,C1} M_{u,C2} \left| \frac{M_{u,C2}^{n-1} + (-1)^n M_{u,C1}^{n-1}}{M_u^{n-1}} \right|.
\]  

(A141)

The triplet term at order \(n\), applied to \((p, u, k)\), is found in equation (A97) by setting (1) \(n_1 = n, n_2 = 0, d_p = n - 1\) and \(d_q = 0\), and (2) \(n_1 = 0, n_2 = n, d_p = n - 1\) and \(d_q = 0\), giving the estimate

\[
\mathcal{S}_{n,3}_{(p,u,k)} \sim \frac{G}{a_k} c_n \left( \frac{a_p}{a_u} \right)^n \left( \frac{a_u}{a_k} \right)^n \left( \frac{a_k}{a_p} \right)^n \left( \frac{a_p}{a_u} \right)^n \left| \frac{M_{p,C2}^{n-1} + (-1)^n M_{p,C1}^{n-1}}{M_p^{n-1}} \right|.
\]  

(A142)

Therefore,

\[
\mathcal{S}_{n,3}_{(p,u,k)} \sim \frac{n M_{\text{CS}(p)} M_{p,C1} M_{p,C2}}{M_u} \left| \frac{M_{p,C2}^{n-1} M_p + (-1)^n M_{p,C1}^{n-1}}{M_p^{n-1}} \right| a_u \left( \frac{a_u}{a_p} \right)^{n+1}.
\]  

(A143a)

\[
\mathcal{S}_{n,3}_{(u,k)} \sim \frac{n M_{\text{CS}(u)} M_{u,C1} M_{u,C2}}{M_p} \left| \frac{M_{u,C2}^{n-1} M_u + (-1)^n M_{u,C1}^{n-1}}{M_u^{n-1}} \right| a_k \left( \frac{a_k}{a_u} \right)^{n+1}.
\]  

(A143b)

Note that for \(n = 3\), these estimates, apart from any dependence on the eccentricities, reduce to equations (12) and (13). We assume a nested planetary system with stellar mass \(M_*\) and planetary mass \(m_p\) such that \(m_p/M_* = \tilde{q} \ll 1\), and semimajor axis ratios \(a_p/a_u = a_u/a_k = \alpha \ll 1\). In this case, \(M_{p,C1} = M_*, M_{p,C2} = m_p, M_{u,C1} = M, M_{u,C2} = m_u, M_{k,C1} = M_*, M_{k,C2} = m_k\). This gives

\[
\mathcal{S}_{n,3}_{(p,u,k)} \sim n \tilde{q} \alpha^n.
\]  

(A144a)

\[
\mathcal{S}_{n,3}_{(u,u)} \sim n \tilde{q} \alpha^{n-1}.
\]  

(A144b)

(note that \(|M_{p,C2}^{n-2} M_p + (-1)^n M_{p,C1}^{n-2} M_p| \approx |m_p^{n-2} M_* + (-1)^n M_*^{n-2} M_0| \approx M_*^{n-1} \).)

In Fig. A2, we show the ratios given by equations (A144) as a function of \(n\), assuming \(\tilde{q} = 10^{-3}\) (i.e. order Jupiter-mass planets around a solar-mass star), and various values of \(\alpha\). The Hamiltonian ratios decrease strongly for increasing \(n\) and decreasing \(\alpha\). For the smallest applicable \(n\), \(n = 3\), and \(\alpha = 0.5\), the ratios are \(< 10^{-3}\), showing that the triplet terms are small.
More generally, and less quantitatively, equation (A97) shows that for nested planetary systems, the non-binary terms, in contrast to pairwise binary terms, are multiplied by mass ratio factors \[ \frac{M_{pl}}{M_{\star}} \CS(p) \approx \frac{d_{pl}}{M_{pl}} \approx (\frac{m_{pl}}{M_{\star}})^{d_{pl}} \ll 1, \] with \( 1 \leq d_{pl} \leq n - 2 \). Also, note that for planetary systems, the quantity \( A_{\phi_{k},CS(p)}^{(d_{pl})} \) is approximately the same for pairwise and non-pairwise terms. Furthermore, the function \( \beta_n \) (cf. equation A139) is generally smaller for non-binary pairs compared to adjacent binary pairs, because in addition to ratios of semimajor axes of adjacent pairs, the non-binary pair terms also include ratios of semimajor axes of non-adjacent pairs (e.g. equation A142 contains the ratio \( a_{pl}/a_k \ll a_{pl}/a_k \)). We conclude that for nested planetary systems, the non-binary pair terms are generally small compared to the pairwise binary terms applied to adjacent binaries.

A7 Ad hoc expression for the 1PN Hamiltonian

In the PN approximation, corrections to Newtonian gravity due to general relativity are included by adding terms of order \( (v/c)^{n} \), where \( v \) is the orbital velocity and \( c \) is the speed of light. To lowest order in \( (v/c) \), the \( N \)-body equations of motion are known and have been derived by Lorentz & Droste (1917) and Einstein, Infeld & Hoffmann (1938). They give rise to a 1PN Hamiltonian that is conserved to order \( (v/c)^2 \).

For the hierarchical three-body problem, the 1PN Hamiltonian was expanded in binary separation ratios and orbit averaged by Naoz et al. (2013b). In the latter paper, it was found that, in addition to terms corresponding to separate precession in the inner and outer orbits, there is also a term associated with both inner and outer binaries, i.e. an ‘interaction’ term.

Here, we do not attempt to derive, from first principles, the generalized 1PN Hamiltonian \( H_{1PN} \) for hierarchical \( N \)-body systems. Rather, we construct an ad hoc expression by assuming that the dominant terms in \( H_{1PN} \) are given by terms which, individually, depend on only one binary, and which give rise to the well-known rate of precession in the 1PN two-body problem. Extrapolating from e.g. the results of Naoz et al. (2013b), these terms for a binary \( k \) should have the form

\[
H_{1PN, k} = -\frac{3G^2 M_{k} C_1 M_{k} C_2 M_{k}}{c^2 a_{k}^{2} (1 - e_{k}^2)^{1/2}}.
\]

From the equations of motion (cf. equation 17), it follows that the precession associated with equation (A145), which only depends on \( e_{k} \), is

\[
\frac{d e_{k}}{dt} = \frac{2\pi}{t_{1PN}} j_{k} \times e_{k},
\]

i.e. \( e_{k} \) precesses around \( j_{k} \) with time-scale \( t_{1PN} \). The latter is given by

\[
t_{1PN} = \frac{1}{3} P_{orb, k} (1 - e_{k}^2) \frac{a_{k}}{r_{g, k}},
\]

where the orbital period is \( P_{orb, k} = 2\pi \sqrt{a_{k}^3/(GM_{k})} \) and the gravitational radius is \( r_{g, k} = GM_{k}/c^2 \).

Therefore, our assumed 1PN Hamiltonian is

\[
H_{1PN} \approx H - \sum_{k \in B} 3G^2 M_{k} C_1 M_{k} C_2 M_{k}
\frac{3G^2 M_{k} C_1 M_{k} C_2 M_{k}}{c^2 a_{k}^{2} (1 - e_{k}^2)^{1/2}},
\]

where \( H \) is the Newtonian part given by equation (A101). Evidently, in this form, orbit averaging of equation (A148) only affects \( H \).
