(Received 28 February 2014; revised manuscript received 14 October 2014; published 15 December 2014)

We report a weak line at 3.52 ± 0.02 keV in x-ray spectra of the Andromeda galaxy and the Perseus galaxy cluster observed by the metal-oxide-silicon (MOS) and p-n (PN) CCD cameras of the XMM-Newton telescope. This line is not known as an atomic line in the spectra of galaxies or clusters. It becomes stronger towards the centers of the objects; is stronger for Perseus than for M31; is absent in the spectrum of a deep “blank sky” data set. Although for each object it is hard to exclude that the feature is due to an instrumental effect or an atomic line, it is consistent with the behavior of a dark matter decay line. Future (non-)detections of this line in multiple objects may help to reveal its nature.

The nature of dark matter (DM) is a question of crucial importance for both cosmology and for fundamental physics. As neutrinos—the only known particles that could be DM candidates—are too light to be consistent with various observations [1–4], it is widely anticipated that new particles should exist. Although many candidates have been put forward (see, e.g., Ref. [5]), little is known experimentally about the properties of DM particles: their masses, lifetimes, and interaction types remain largely unconstrained. A priori, a given DM candidate can possess a decay channel if its lifetime exceeds the age of the Universe. Therefore, the search for a DM decay signal provides an important test to constrain the properties of DM in a model-independent way. For fermionic particles, one should search above the Tremaine-Gunn limit [1] (∼300 eV). If the mass is below 2mₑc², such a fermion can decay to neutrinos and photons with energy Eᵣ = ½mₑmₑ [6]. One can search for such particles in x rays [7,8] (see Ref. [9] for a review of previous searches). For each particular model, the particle’s parameters are related by the requirement to provide the correct DM abundance. For example, for one very interesting DM candidate—the right-handed neutrino—this requirement restricts the mass range to 0.5–100 keV [9,10]. A large part of the available parameter space for sterile neutrinos is consistent with all astrophysical and cosmological bounds [11], and it is important to probe it further.

The DM decay line is much narrower than the spectral resolution of the existing x-ray telescopes and, as previous searches have shown, should be rather weak. The x-ray spectra of astrophysical objects are crowded with weak atomic and instrumental lines, not all of which may be known. Therefore, even if the exposure of available observations continues to increase, it is hard to exclude an astrophysical or instrumental origin of any weak line found in the spectrum of an individual object. However, if the same feature is present in the spectra of many different objects, and its surface brightness and relative normalization between objects are consistent with the expected behavior of the DM signal, this can provide much more convincing evidence about its nature.

The present Letter takes a step in this direction. We present the results of the combined analysis of many XMM-Newton observations of two objects at different redshifts—the Perseus cluster (z = 0.0179 [12]) and the Andromeda galaxy (M31, z = −0.001), a Local Group member—together with a long exposure “blank sky” data set. (Each of the data sets used in previous decaying DM searches in M31 [13–17] had less statistics than we use. The nondetection of any signal in these works does not come in contradiction with our results.) We present the detection of a significant unmodeled excess at 3.52 ± 0.02 keV (rest frame) in both objects. We study its behavior and establish that it is consistent with a DM interpretation. However, as the line is weak (~ 4σ in the combined data set) and the uncertainties in DM distribution are significant, positive detections or strong constraints from more objects are clearly needed to determine its nature.

Below we summarize the details of our data analysis and then discuss the results and caveats.

Data analysis.—We use the data obtained with the metal-oxide-silicon (MOS) [18] and p-n (PN) CCD [19] cameras of XMM-Newton (“XMM” in what follows). We use SAS v.13.0.0 [20] to reduce the raw data and filter the data for soft solar protons [21,22] using the ESPFILT procedure. Because residual soft proton flares can produce weak line-like features in the spectra at positions where the effective area is non-monotonic (see, e.g., Ref. [23]), we apply the procedure described in Ref. [24], based on the comparison

0031-9007/14/113(25)/251301(6) 251301-1 © 2014 American Physical Society
of high-energy count rates for “in-field-of-view” (in-FOV) 
(10–15 arcmin off center) and out-FOV CCD regions [25]. 
We selected only observations where the ratio of 
$F_{\text{in}} - F_{\text{out}} < 1.15$. (Reference [24] argued that 
$F_{\text{in}} - F_{\text{out}} < 1.3$ is a sufficient criterion for flare removal. We find by visual 
inspection of the resulting spectra that a stricter criterion 
is needed to reduce artificial linelike residuals [23,26]. 
Lowering the threshold further is not feasible as the statistical 
error bars on the value of $F_{\text{in}} - F_{\text{out}}$ are of the order of 5%.)

Combined observation of M31.—We use $\sim 2$ Msec of 
raw exposure observations of M31 within the central 1.5° 
(see Supplemental Material [27], Table II). We select from 
the XMM archive 29 MOS observations offset less than 
1.5° from the center of M31, and 20 MOS observations with 
offsets 23.7° – 55.8° that passed our criterion for residual 
contamination. Not enough PN observations passed this 
test to include them. The central and off-center observations 
were co-added separately with the ADDSPEC routine 
from FTOOLS [31]. The resulting spectra were binned by 
60 eV. This bin size is a factor $\sim 2$ smaller than the spectral 
resolution of the XMM at these energies, which makes the 
bins roughly statistically independent.

Background modeling.—We model the contribution of 
the instrumental (particle induced) background by a combina-
tion of an unfolded power law plus several narrow 
Gaussian lines. The positions and normalizations of the 
lines were allowed to vary freely and the most prominent 
instrumental $K\alpha$ lines (Cr, Mn, K, Fe, Ni, Ca, Cu) and Fe $K\beta$ 
have been recovered. The width of the Gaussians was 
fixed at 1 eV (an infinitely thin line for the XMM spectral 
resolution). We verified that allowing the line widths to 
 vary freely leaves the results unchanged. We restrict our 
modeling to the energy interval 2–8 keV [32]. The combined 
emission of unresolved point sources at these energies is 
modeled by a POWERLAW [33]. Several linelike residuals 
around 2.4 keV and 3.0 keV were identified as Ar and S line 
complexes and the corresponding thin (1 eV width) lines 
were added to the model. We verified that adding another 
POWERLAW component to model the contribution of the 
extragalactic x-ray background [24,32] does not improve 
the quality of fit and does not change the structure of the 
residuals.

Result.—The resulting spectrum of the central observations 
shows a group of positive residuals around 3.5 keV (Fig. 1). 
Adding a thin Gaussian line at that energy reduces 
the total $\chi^2$ by $\sim 13$, see Table I (more than 3$\sigma$ significance 
for the extra 2 DOF). Examination of MOS1 and MOS2 
observations individually finds the line in both cameras 
with comparable flux. For the off-center observations, none 
of the cameras show any detectable residual in the energy 
range 3.50–3.56 keV. The 2$\sigma$ upper bound on the flux is 
given in Table I.

Perseus cluster.—If the candidate weak signal is of 
anastrophysical (rather than instrumental) origin, we should 
be able to detect its redshift. To this end we have chosen the 
neighboring Perseus cluster (Abell 426). At its redshift the line’s 
centroid would be shifted by 63 eV. As the position of the 
line is determined with about 30 eV precision, one can 
expect to resolve the line’s shift with about 2$\sigma$ significance.

We took 16 off-center observations of the Perseus cluster 
(see Supplemental Material [27], Table II) and processed 
them in the same way as for M31. The flare removal 
procedure left PN camera exposure, therefore, we also use 
PN data.

Background modeling.—The resulting spectra were then 
added together and fitted to the combination of VMKAL 
(with free abundances for Fe, Ni, Ar, Ca and S) plus 
(extragalactic) POWERLAW. The instrumental background 
was modeled as in the M31 case.

Results.—The fit shows significant positive residuals at 
energies around 3.47 keV (in the detector frame). Adding a
ZGAUSS model with the redshift of the cluster improves the fit by $\Delta \chi^2 = 9.1$. The line’s position is fully consistent with that of M31 (Table I). If we fix the position of the line to that of M31 and allow the redshift to vary, $z = 0$ provides a worse fit by $\Delta \chi^2 = 3.6$ and its best-fit value is $(1.73 \pm 0.08) \times 10^{-2}$—close to the value $z = 0.0179$ which we have used.

Blank-sky data set.—To further study the origin of the new line and possible systematic effects we combine XMM blank-sky observations from Refs. [34,35] with observations of the Lockman Hole [36]. The data were reduced similarly to the other data sets. Figure 3 shows the combined spectrum. A data set with such a large exposure requires special analysis (as described in Ref. [26]). This analysis did not reveal any linelike residuals in the range $3.45–3.58$ keV with the $2\sigma$ upper bound on the flux being $7 \times 10^{-7}$ counts s$^{-1}$ cm$^{-2}$. The closest detected linelike feature ($\Delta \chi^2 = 4.5$) is at $3.67^{+0.10}_{-0.05}$ keV, consistent with the instrumental Ca $K\alpha$ line. (Previously this line had only been observed in the PN camera [19]).

**Combined fit of M31 + Perseus.—**Finally, we have performed a simultaneous fit of the on-center M31 and Perseus data sets (MOS), keeping a common position of the line (in the rest frame) and allowing the line normalizations to be different. The line improves the fit by $\Delta \chi^2 = 25.9 - 4.4\sigma$ significance (Table I).

**Results and discussion.—**We identified a spectral feature at $E = 3.52 \pm 0.02$ keV in the combined data set of M31 and Perseus with a statistical significance $4.4\sigma$ which does not coincide with any known line. Next we compare its properties with the expected behavior of a DM decay line.

The observed brightness of a decaying DM should be proportional to its column density $S_{\text{DM}} = \int \rho_{\text{DM}} d\ell$—integral along the line of sight of the DM density distribution—and inversely proportional to the radiative decay lifetime $\tau_{\text{DM}}$:

$$F_{\text{DM}} \approx 2.0 \times 10^{-6} \frac{\text{counts}}{\text{cm}^2 \text{sec}} \left( \frac{\Omega_{\text{FOV}}}{500 \text{ arcmin}^2} \right) \times \left( \frac{S_{\text{DM}}}{500 \text{ M}_\odot/\text{pc}^2} \right) \frac{10^{26} \text{ s}}{\tau_{\text{DM}}} \left( \frac{m_{\text{DM}}}{1\text{ keV}} \right).$$

**FIG. 2** (color online). The line’s brightness profile in M31 (left) and the Perseus cluster (right). A NFW DM distribution is assumed, the scale $r_s$ is fixed to its best-fit values from Ref. [37] (M31) or Ref. [40] (Perseus) and the overall normalization is adjusted to pass through the left-most point.
our observations of Perseus go beyond expected line distribution from DM decay using the NFW center observations we constrain the spatial profile of the angle the lifetime is related to its interaction strength (mixing angle). Therefore, the ratio of expected signals between Perseus and the center of M31 can be 0.1–3.0, consistent with the ratio of measured fluxes 0.7–2.7.

For the Perseus cluster the observations can be grouped in three radial bins by their off-center angle. For each bin we fix the line position to its average value across Perseus (3.47 ± 0.07 keV). The obtained line fluxes together with 1σ errors are shown in Fig. 2. For comparison, we draw the expected line distribution from DM decay using the NFW profile of Ref. [40] [best fit value \( r_s = 360 \) kpc (\( c \approx 5 \))]. Black solid line; upper bound \( r_s = 872 \) kpc (\( c \approx 2 \)), black dashed line). The isothermal \( \beta \) profile from Ref. [41] is shown in magenta. The surface brightness profile follows the expected DM decay line’s distribution in Perseus.

Finally, we compare the predictions for the DM lifetime from the two objects. The estimated column density within the central part of M31 ranges between \( \delta \sim 200–1000 \) M\( _\odot \)/pc\(^2\) with the average value being around \( 600 \) M\( _\odot \)/pc\(^2\) [23]. The column density of clusters follows from the c-M relation [42–44]. Considering the uncertainty on the profile and that our observations of Perseus go beyond \( r_s \), the column density in the region of interest is within \( \delta \sim (100–600) \) M\( _\odot \)/pc\(^2\). Therefore, the ratio of expected signals between Perseus and the center of M31 can be 0.1–3.0, consistent with the ratio of measured fluxes 0.7–2.7.

If DM is made of right-handed (sterile) neutrinos [45], the lifetime is related to its interaction strength (mixing angle):

\[
\tau_{DM} = \frac{1024\pi^4}{9\alpha G_F \sin^2(2\theta) m_{DM}^5} = 7.2 \times 10^{29} \text{ sec} \left[ \frac{10^{-9}}{\sin^2(2\theta)} \right] \left[ 1\text{keV} \right]^5.
\]

Using the data from M31 and taking into account uncertainties in its DM content, we obtain the mass \( m_{DM} = 7.06 \pm 0.06 \) keV and the mixing angle in the range \( \sin^2(2\theta) = (2–20) \times 10^{-11} \) (taking the column density \( \delta = 600 \) M\( _\odot \)/pc\(^2\) and using only statistical uncertainties on flux we would get \( \sin^2(2\theta) = 4.9_{-1.3}^{+1.6} \times 10^{-11} \)). This value is fully consistent with previous bounds, Fig. 4. Moreover, it is intriguing that this value is consistent with the result of [46]. Indeed, our value of \( \sin^2(2\theta) \) is based on completely independent analysis of the signal from M31 and our estimates for its DM content, whereas the result of Ref. [46] is based on the signal from stacked galaxy clusters and on the weighted DM column density from the full sample.

These values of \( \sin^2(2\theta) \) mean that sterile neutrinos should be produced resonantly [48–50], which requires the presence of significant lepton asymmetry in primordial plasma at temperatures few hundreds MeV. This produces restrictions on parameters of the ε-MSM [10].

The position and flux of the discussed weak line are inevitably subject to systematical uncertainties. There are two weak instrumental lines (Kα Ca at 3.31 keV and Kα Na at 3.69 keV), although formally their centroids are separated by more than 4σ. Additionally, the region below
3 keV is difficult to model precisely, especially at large exposures, due to the presence of the absorption edge and galactic emission. However, although the residuals below 3 keV are similar between the M31 data set (Fig. 1) and the blank sky data set (Fig. 3), the line is not detected in the latter.

If the feature were due to an unmodeled wiggle in the effective area, its flux would be proportional to the continuum brightness and the blank-sky data set would have exhibited a 4 times smaller feature with roughly the same significance (see Supplemental Material [27], Section B). In addition, the Perseus line would not be properly redshifted.

The properties of this line are consistent (within uncertainties) with the DM interpretation. To reach a conclusion about its nature, one will need to find more objects that give a detection or where nonobservation of the line will put tight constraints on its properties. The forthcoming Astro-H mission [51] has sufficient spectral resolution to spectrally resolve the line against other nearby features and to detect the candidate line in the “strong line” regime [52]. In particular, Astro-H should be able to resolve the Milky Way halo’s DM decay signal and therefore all its observations can be used. Failure to detect such a line will rule out the DM origin of the Andromeda/Perseus signal presented here.

We thank D. Malyshev for collaboration; A. Neronov for useful critical comments; M. Shaposhnikov and M. Lovell for reading the manuscript and providing valuable comments. We also thank K. Abazajian, J. Beacom, and M. Kaplinghat for their comments. The work of D. I. was supported by the Jet Propulsion Laboratory, California Institute of Technology in Ukraine, and the grant of President of Technology of the National Academy of Sciences of Ukraine Grant SCOPE IZ7370-152581, the Program of Cosmic Fundamentals of Science program, that cites additional Refs. [28–30] as well as Ref. [18].

Note added.—Recently Ref. [46] appeared, claiming a detection of a spectral feature at the same energy from a collection of galaxy clusters. Our analyses are independent, based on different data sets, but the results are fully consistent.
