Chaper 2 Toxicity and accumulation of Cu and ZnO nanoparticles in Daphnia magna

Yinlong Xiao, Martina G. Vijver, Guangchao Chen, Willie J. G. M. Peijnenburg

Published in Environmental Science and Technology, 2015, 49, 4657–4664

Abstract
There is increasing recognition that the wide use of nanoparticles, such as Cu (CuNPs) and ZnO nanoparticles (ZnONPs), may pose risks to the environment. Currently there is insufficient insight in the contribution of metal-based nanoparticles and their dissolved ions to the overall toxicity and accumulation. To fill in this gap, we combined the fate assessment of CuNPs and ZnONPs in aquatic test media with the assessment of toxicity and accumulation of ions and particles present in the suspensions. It was found that at the LC50 level of Daphnia magna exposed to the nanoparticle suspensions, the relative contributions of ions released from CuNPs and ZnONPs to toxicity were around 26% and 31%, respectively, indicating that particles rather than the dissolved ions were the major source of toxicity. It was additionally found that at the low exposure concentrations of CuNPs and ZnONPs (below 0.05 and 0.5 mg/L, respectively) the dissolved ions were predominantly accumulated, whereas at the high exposure concentrations (above 0.1 mg/L and 1 mg/L, respectively), particles rather than the released ions played a dominant role in the accumulation process. Our results thus suggest that consideration on the contribution of dissolved ions to nanoparticle toxicity needs to be interpreted with care.

Key words: copper nanoparticles, zinc oxide nanoparticles, acute toxicity, accumulation, Daphnia magna

2.1 Introduction
Nanoparticles (NPs) are defined as particles with at least one dimension between 1 and 100 nm. Due to the small size of NPs, they usually show unique physicochemical properties, such as high surface area and high mechanical strength. NPs are increasingly used in many applications. Cu nanoparticles (CuNPs) and ZnO nanoparticles (ZnONPs) have been manufactured on a large scale in different areas. For instance, CuNPs have been widely employed in catalysis and batteries (Zhang et al., 2005; Radi et al., 2010), and ZnONPs have been extensively used in cosmetics and UV-absorbers (Becheri et al., 2008). Like other types of NPs, the recent increasing use of CuNPs and ZnONPs has also started to induce concern on their toxicity to some specific aquatic organisms, such as mussel (Hu et al., 2014), and juvenile carp (Hao et al., 2013). Hence, there is a necessity to investigate the underlying processes resulting in the toxicity of CuNPs and ZnONPs to aquatic organisms.

Toxicity of NPs may be exerted by particles (designated as NP_{(particle)} hereafter) (Cronholm et al., 2013; Santo et al., 2014), by dissolved ions released from NPs (designated as NP_{(ion)} hereafter) (Jo et al., 2012; Adam et al., 2014a), or by both NP_{(particle)} and NP_{(ion)} (Navarro et al., 2008). Undoubtedly, determining the contribution of NP_{(particle)} and NP_{(ion)} to the overall
totoxicity of nanoparticle suspensions (designated as NP_{total} hereafter), is a crucial step in assessing and managing the possible adverse effects of NPs. Based on the existing literature, it is still hard to get a uniform conclusion about what is the major source of toxicity of NPs. This may be due to the fact that many factors can affect the toxicity performance of NPs, not only the characteristics of the NPs, but also the exposure conditions (Heinlaan et al., 2008). Thus the underlying physicochemical mechanisms leading to the toxicity of different NPs to aquatic organisms should be investigated on a case by case basis, which suggests that more research should be performed to make a comprehensive consideration about this research question.

In the present study, *Daphnia magna* was selected as a model organism. The 48 h toxicity of CuNPs and ZnONPs to *D. magna* was determined. To analyze the relative contribution of NP_{ion} to the overall toxicity of CuNPs and ZnONPs (designated as CuNP_{total} and ZnONP_{total} hereafter, respectively), centrifugation and filtering methods were combined to separate the dissolved ions released from the NPs. Subsequently, the 48 h toxicity of the supernatants only containing NP_{ion} to daphnids was investigated. In order to test whether using metal salts as substitutes for the dissolved ions released from NPs is effective, the toxicity of dissolved Cu released from CuNPs (designated as CuNP_{ion} hereafter) and dissolved Zn released from ZnONPs (designated as ZnONP_{ion}, hereafter) to daphnia neonates was compared to the toxicity of Cu(NO_3)_2 and Zn(NO_3)_2. Additionally, the issue which species, NP_{particle} or NP_{ion}, plays a major role in the accumulation process was investigated in this study.

### 2.2 Materials and methods

#### 2.2.1 Test materials, test medium and test species

CuNPs with a nominal size of 50 nm (advertised specific surface area, 6-8 m^2/g; purity, 99.8%) and ZnONPs with a nominal size of 43 nm (advertised specific surface area, 27 m^2/g; purity, 99.5%) were purchased from IoLiTec (Heibronn, Germany). Both CuNPs and ZnONPs were spherically shaped. Cu(NO_3)_2 and Zn(NO_3)_2 were purchased from Sigma Aldrich (Zwijndrecht, The Netherlands).

Stock nanoparticle suspensions and salts were freshly prepared in ISO standard test medium (STM) after 20 min sonication in a water bath sonicator. The STM used in this study (pH 7.8 ± 0.2) contained (mg/L MilliQ water): CaCl_2·2H_2O: 294; MgSO_4·7H_2O: 123.25; NaHCO_3: 64.75; KCl: 5.75 (Griffitt et al., 2007).

*D. magna*, originally obtained from the Dutch National Institute for Public Health and the Environment (RIVM), was selected as the test species. Artificial ElendtM4 medium was used to culture *D. magna* (OECD, 2004), which was refreshed three times a week. The test organisms were cultured in plastic containers at a density of 1 individual/10 ml of ElendtM4 medium under a 16:8 light-dark cycle (20 ± 1 °C) and fed with *Pseudokirchneriella subcapitata* every two days.

#### 2.2.2 Physicochemical analysis

The morphology and size of CuNPs and ZnONPs in STM were characterized by using transmission electron microspectroscopy (TEM, JEOL 1010, JEOL Ltd., Japan). The samples
were analyzed directly (which was around 1 h after submerging NPs into the STM, to which we will refer to as 1 h) and after 24 h and 48 h. The size distribution of suspensions of CuNPs and ZnONPs at 1 mg/L were analyzed at 1 h, 24 h and 48 h after incubation in the test medium by dynamic light scattering (DLS) on a zetasizer Nano-ZS instrument (Malvern Instruments Ltd., UK). At the same point, the zeta potential of each suspensions was determined by the ZetaPALS software based on the Smoluchowski equation. The actual exposure concentrations of CuNPs and ZnONPs, as well as Cu(NO$_3$)$_2$ and Zn(NO$_3$)$_2$ in the STM were determined by Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES) after digestion in 65% HNO$_3$ for at least 1 day. In order to obtain the CuNP$_{\text{ion}}$ and ZnONP$_{\text{ion}}$, the two nanoparticle suspensions firstly were centrifuged at 30392 g for 30 min at 4 °C (Sorvall RC5Bplus centrifuge, Fiberlite F21-8 × 50y rotor) to obtain the supernatants, which were then filtered through a syringe filter with 0.02 µm pore diameter (Antop 25, Whatman). We also applied ultracentrifugation and then performed DLS to confirm that the concentration of NP$_{\text{particle}}$ in the supernatants obtained by centrifugation at 30392 g for 30 min at 4 °C and subsequent filtration through a syringe filter with 0.02 µm pore diameter was less than the detection limit, and the detailed information on the confirmation is given in the Supplementary Information 2.1.

2.2.3 Assessment of the 48 h release profiles of dissolved Cu and Zn
The release profiles of dissolved Cu released from the CuNPs at 0.1 mg/L and 10 mg/L for a maximum of 48 h of exposure, and the release of dissolved Zn released from the ZnONPs at 1 mg/L and 10 mg/L for a maximum of 48 h of exposure in the STM were investigated. At different times, namely after being exposed to the medium for 1, 12, 24, 36 and 48 h, CuNPs and ZnONPs samples were centrifuged at 30392 g for 30 min at 4 °C (Sorvall RC5Bplus centrifuge, Fiberlite F21-8 × 50y rotor) and then the supernatants were filtered through a syringe filter with 0.02 µm pore diameter (Antop 25, Whatman). Subsequently, the Cu concentrations and Zn concentrations in the supernatants after filtration were measured by ICP-OES. To analyze the losses of NPs and NP$_{\text{ion}}$ after centrifugation and filtration, experiments were conducted and the detailed information on the analysis is given in Supplementary Information 2.2.

2.2.4 The 48-h acute toxicity test
OECD Guideline 202 with slight modifications was used to test the acute toxicity of the two nanoparticle suspensions. Before the start of the acute toxicity test, daphnids were kept in the STM for 1-2 h to evacuate their guts. The toxicity tests were performed using neonates (< 24 h). Five individuals were transferred into a test vial, containing 20 ml of CuNPs or ZnONPs, or metal salt solutions, or control. Based on the results of range finding experiments, exposure concentrations from 0.02 mg/L to 0.16 mg/L for CuNPs and from 0.4 mg/L to 2.6 mg/L for ZnONPs, as well as from 0.01 mg/L to 0.06 mg/L for Cu(NO$_3$)$_2$ and from 0.5 mg/L to 1.5 mg/L for Zn(NO$_3$)$_2$ were selected. Each test was composed of 8 to 10 different exposure concentrations and each exposure concentration was tested with 4 replicates. Daphnids were incubated under a 16:8 h light/dark photoperiod (20 ± 1 °C) without feeding during the 48 h exposure period. To avoid significant changes in the concentrations of the nanoparticle suspensions, the exposure media were refreshed every 24 h.
Besides investigating the toxicity of the suspensions of CuNPs and ZnONPs, the relative contribution of NP\textsubscript{particle} and NP\textsubscript{ion} to the toxicity induced by the suspensions of CuNPs and ZnONPs was also examined. In order to better simulate the contribution of CuNP\textsubscript{ion} and ZnONP\textsubscript{ion} to the overall toxicity, the supernatants after filtration of the two NPs in the STM were prepared as described above. The neonate daphnids were then exposed to the supernatants according to the same procedures as described above. To compare with the toxicity of the freshly prepared solutions of CuNP\textsubscript{ion} and ZnONP\textsubscript{ion}, the toxicity of Cu(NO\textsubscript{3})\textsubscript{2} and of Zn(NO\textsubscript{3})\textsubscript{2} to D. magna was tested with the same procedures as described above, as well.

2.2.5 Accumulation experiments

Experiments were conducted to identify the accumulation profiles of D. magna exposed to CuNPs, ZnONPs and their corresponding dissolved ions. In brief, D. magna (8 d old) were transferred to the suspensions of CuNPs and ZnONPs at a density of 1 individual/10 ml with 3 replicates. The concentrations of CuNPs applied in the accumulation experiments were 0.1 and 0.05 mg/L and the concentrations of ZnONPs were 1 and 0.5 mg/L, respectively. These concentrations were selected based on the results of the acute toxicity tests described above, which concerned the LC50. Adult daphnids (8 d old) were utilized. We first of all selected adult daphnids, because they are more easy to handle, compared to neonates. Moreover, due to physiological (e.g., surface-volume ratio) and behavioral aspects adults are often less susceptible to NPs compared to juvenile and neonate life stages in ecotoxicity studies (Ates et al., 2013; Wang et al., 2013), which allowed us to analyze accumulation characteristics at high concentration of nanoparticle suspensions. Finally, it is advantageous to use adults as growth dilution may be reduced (He et al., 2007; Karimi et al., 2007). In order to distinguish between the contribution of NP\textsubscript{particle} and NP\textsubscript{ion} to accumulation, D. magna were also exposed to the supernatants of the CuNPs at the initial CuNPs concentrations of 0.1 mg/L and 0.05 mg/L and to the supernatants of ZnONPs at the initial ZnONPs concentrations of 1 mg/L and 0.5 mg/L. These supernatants were prepared as described above. Many recent studies have shown that the accumulation of NPs in D. magna is a rapid process (Tab et al., 2012; Zhao and Wang, 2012; Li et al., 2013). Hence, a 48 h exposure period was selected in our test. Similar to the acute toxicity tests, the accumulation experiments were conducted under a 16:8 h light/dark photoperiod (20 ± 1 ℃) without feeding during the 48 h exposure period. The exposure media were refreshed every 24 h. After the 48 h exposure period, 10 mobile daphnids were sampled from each exposure medium and they then were transferred to MilliQ water for 1-3 min. Subsequently, they were rinsed three times with fresh MilliQ water. After rinsing, they were dried at 80 ℃ overnight in pre-weighed glass containers before weighing on a microbalance and then digested in 69% HNO\textsubscript{3} at 80 ℃ overnight. The Cu and Zn concentrations in the digested samples were subsequently determined by ICP-OES.

To clarify in this study, accumulation is defined as the absorbed and adsorbed metals after rinsing the daphnids. As after rinsing the daphnids with MilliQ water, NPs may not be completely removed, and may still be adsorbed to the outside of organisms. Surface adsorption of NPs onto the exterior of D. magna limits their biological activity and also may pose risks to their health development. For example, Dabrunz et al. (2011) found that
adsorbed NPs caused mortality through reducing the molting rate of *D. magna*. Hence, both absorbed and adsorbed fraction are considered in this study.

### 2.2.6 Relative contribution to toxicity of NP\(_{\text{(particle)}}\) and NP\(_{\text{(ion)}}\)

The neonates of *D. magna* were exposed to the nanoparticle suspensions containing a mixture of NP\(_{\text{(particle)}}\) and NP\(_{\text{(ion)}}\). The behavior and toxicity of chemicals in a mixture may not conform to that predicted from data on pure compounds (Altenburger et al., 2003). Complicated and remarkable changes in the apparent properties of its constituents can be induced by interactions of components in a mixture, leading to increased or decreased effects compared with the ideal reference case of additive behavior. For evaluation of the joint toxicity of mixtures, the concentration addition (CA) model and the independent action (IA) model are two prominent reference models, both of which have been mechanistically supported by pharmacology (Altenburger et al., 2003). Which model is preferably employed to analyze the combined effects of chemicals in a mixture is based on the mode of action (Altenburger et al., 2003). Specifically, the CA model can be utilized to estimate the combined effects of chemicals in a mixture with a similar mode of action, whereas the IA model is employed to analyze the joint effects of chemicals with dissimilar mode of actions (Altenburger et al., 2003). The response addition model is often used as a synonym for the IA model (Faust et al., 2003). Based on the previous literature, it is widely believed that the modes of actions of NP\(_{\text{(particle)}}\) and NP\(_{\text{(ion)}}\) are likely to be dissimilar (Hua et al., 2014a and 2014b). Thus the response addition model was selected in the present study to calculate the relative contribution to toxicity of NP\(_{\text{(particle)}}\) and NP\(_{\text{(ion)}}\). The response addition model is defined as follows:

\[
E_{\text{total}} = 1 - [(1 - E_{\text{(ion)}})(1 - E_{\text{(particle)}})]
\]

Where \(E_{\text{total}}\) and \(E_{\text{(ion)}}\) represent the toxicity caused by the nanoparticle suspensions and their corresponding released ions (scaled from 0 to 1). In the present study, \(E_{\text{total}}\) and \(E_{\text{(ion)}}\) were quantified experimentally. This makes \(E_{\text{(particle)}}\) as the only unknown, allowing for direct calculation of the effects caused by the NP\(_{\text{(particle)}}\).

### 2.2.7 Statistical analysis

All data are expressed as the mean with the corresponding standard deviation (SD). The LC50 values and 95% confidence intervals (95% CI) were calculated by GraphPad Prism 5 using non-linear regression. Based on normality and homogeneity of variance, statistically significant differences between accumulation groups were determined by *t*-test. The significance level in all calculations was set at \(p < 0.05\).

### 2.3 Results

#### 2.3.1 Physicochemical characterization of CuNPs and ZnONPs

TEM images of CuNPs and ZnONPs are presented in Figure 2.1. The images demonstrate that the CuNPs and ZnONPs used in this study were spherical particles. However, the CuNPs and ZnONPs aggregated intensely into irregular shapes in the STM. DLS was performed for determining the hydrodynamic diameter of the CuNPs and ZnONPs suspended in STM. Data on size distributions after 1, 24 and 48 h are given in Table 2.1. Both NPs aggregated as soon
as being submerged into the STM. The particle size of CuNPs in the STM was found to increase from $568 \pm 72$ nm after 1 h of incubation to $953 \pm 525$ nm after 48 h of incubation and the particle size of ZnONPs shifted from $1154 \pm 252$ nm after 1 h of incubation to $1871 \pm 509$ nm after 48 h of incubation. The zeta potential of the two nanoparticle suspensions increased after NPs being submerged into the medium. The zeta potential of the CuNPs increased from $-14 \pm 4$ after 1 h of incubation to $-4 \pm 2$ after 48 h of incubation. Similarly, the zeta potential of the ZnONPs increased from $-10 \pm 2$ after 1 h of incubation to $-3 \pm 2$ after 48 h of incubation.

### 2.3.2 The 48 h ion release profiles of CuNPs and ZnONPs

The 48 h release profiles of CuNPs of ZnONPs are shown in Figure 2.2. The percentage of CuNP$_{(\text{ion})}$ in the CuNPs suspension at 0.1 mg/L shifted from 18% after 1 h of incubation to 20% after 48 h of incubation. The ZnONPs at 1 mg/L showed a relatively high degree of dissolution. The percentage of the ZnONP$_{(\text{ion})}$ increased from 59% after 1 h of incubation to 65% after 48 h of incubation in the STM. As for the percentages of the CuNP$_{(\text{ion})}$ and ZnONP$_{(\text{ion})}$ in the nanoparticle suspensions at 10 mg/L, both of them remained around 10% during the 48 h of incubation.
2.3.3 The 48 h acute toxicity of CuNPs and ZnONPs

All the exposures of neonate daphnids to the nanoparticle suspensions and their dissolved ions induced significant toxicity (Figure 2.3). CuNP_{total} showed a much lower 48 h LC50 value of 0.093 mg/L (with a 95% CI of 0.86-0.101 mg/L), compared to ZnONP_{total} (0.99 mg/L, with a 95% CI of 0.92-1.07 mg/L). The LC50 value of CuNP_{ion} was 0.030 mg/L (with a 95% CI of 0.027-0.034 mg/L) and the LC50 value of the ZnONP_{ion} was 1.15 mg/L (with a 95% CI of 1.02-1.30 mg/L), which indicated that the CuNP_{ion} was also much more toxic (over 10 times) to D. magna, compared to the ZnONP_{ion}. The dose-response curves for Cu(NO_3)_2 and Zn(NO_3)_2 are also given in Figure 2.3. The LC50 of Cu(NO_3)_2 to the neonates was 0.028 mg/L (with a 95% CI of 0.026-0.029 mg/L), which was similar to the LC50 value of the CuNP_{ion}. Likewise, the LC50 of Zn(NO_3)_2 (1.01 mg/L, with a 95% CI of 0.94-1.09 mg/L) was similar to the LC50 level of the ZnONP_{ion}.

![Figure 2.2](image1.png)

**Figure 2.2** The relative percentages of dissolved Cu released from CuNPs at the concentrations of 0.1 mg/L and 10 mg/L, and of dissolved Zn released from ZnONPs at the concentrations of 1 mg/L and 10 mg/L, during 48 h of incubation in the STM. Data are mean ± SD (n = 3).

![Figure 2.3](image2.png)

**Figure 2.3** Dose-response curves of mortality (%) of D. magna exposed to different concentrations of CuNP_{total}, ZnONP_{total}, CuNP_{ion}, ZnONP_{ion}, Cu(NO_3)_2 and Zn(NO_3)_2 for 48 h. Actual log-transformed Cu or Zn concentrations are plotted on the x-axis. Data are mean ± SD (n = 4).
2.3.4 The 48 h accumulation characteristics of CuNPs and ZnONPs

The accumulation profiles of CuNPs and ZnONPs are shown in Figure 2.4. At the low CuNPs concentration (0.05 mg/L), the overall accumulation of Cu (105 ± 39 μg/g dry weight) in daphnids was higher than the accumulation of the CuNP\textsubscript{(ion)} (49 ± 14 μg/g dry weight). Moreover, at the high CuNPs concentration (0.1 mg/L), the overall accumulation of Cu was 264 ± 60 μg/g dry weight, which was significantly higher than the accumulation of the CuNP\textsubscript{(ion)} (68 ± 15 μg/g dry weight, \( p < 0.05 \)). As for the Zn accumulation, the overall accumulation of Zn at 0.5 mg/L of ZnONPs (558 ± 106 μg/g dry weight) was significantly higher than the accumulation of ZnONP\textsubscript{(ion)} (301 ± 82 μg/g dry weight, \( p < 0.05 \)). Likewise, the overall accumulation of Zn at 1 mg/L of ZnONPs (1345 ± 331 μg/g dry weight) was significantly higher than the accumulation of ZnONP\textsubscript{(ion)} (484 ± 85 μg/g dry weight, \( p < 0.05 \)).

![Figure 2.4](image)

Figure 2.4 The accumulation (μg/g dry wt.) of Cu and Zn in \textit{D. magna} after exposure for 48 h to 0.05 mg/L and 0.1 mg/L of CuNP suspensions and to 0.5 mg/L and 1.0 mg/L of ZnONP suspensions, the corresponding dissolved Cu released from the above concentrations of CuNPs, and the corresponding dissolved Zn released from the above concentrations of ZnONPs. The different letters indicate the significant differences of accumulation levels, \( p < 0.05 \). The \( p \)-value between different accumulation groups was determined by means of the \( t \)-test.

2.3.5 Relative contribution of NP\textsubscript{(particle)} and NP\textsubscript{(ion)} to toxicity and accumulation

The relative contribution of NP\textsubscript{(particle)} and NP\textsubscript{(ion)} to the overall toxicity at the LC50 levels of CuNPs and ZnONPs to neonates is given in Table 2.2. The relative contribution of CuNP\textsubscript{(ion)} to toxicity was only 26%, whereas CuNP\textsubscript{(particle)} accounted for about 74% of the relative contribution to mortality at the LC50 level of CuNP\textsubscript{(total)}. ZnONP\textsubscript{(ion)} only contributed a fraction of 31% to the overall toxicity, compared to the contribution of ZnONP\textsubscript{(particle)}. In addition, the relative contribution to accumulation of NP\textsubscript{(particle)} and NP\textsubscript{(ion)} is calculated and shown in Table 2.3. At the low concentration of CuNPs (0.05 mg/L), CuNP\textsubscript{(ion)} contributed around 52% to the overall accumulation, whereas at the concentration of 0.1 mg/L of CuNPs, CuNP\textsubscript{(ion)} merely accounted for about 28%. Likewise, at the low concentration of ZnONPs (0.5 mg/L), ZnONP\textsubscript{(ion)} could explain about 53% of the overall Zn accumulation, while at the
Toxicity and accumulation of Cu and ZnO nanoparticles in Daphnia magna

high concentration (1 mg/L of ZnONPs), ZnONP\textsubscript{(ion)} only contributed around 36% to the overall Zn accumulation.

2.4 Discussion

2.4.1 Ion release profiles of CuNPs and ZnONPs

In this study, ZnONPs were demonstrated to be more soluble than CuNPs. ZnONPs showed an especially rapid dissolution process at a low concentration in the STM. We found that 59% of the ZnONPs at 1 mg/L were already dissolved after 1 h of incubation (Figure 2.2). This result was similar with the recent result obtained by Adam et al. (2014b), who detected that ZnONPs (with a nominal size of 30 nm) showed 60% of dissolution within 1-2 h in the ISO medium. However, it is worth to note that the percentage of dissolved ZnONP\textsubscript{(ion)} is reported to vary considerably in the existing literature. For example, Merdzan et al. (2014) found that the percentage of dissolved Zn released from bare ZnONPs with a nominal size of 20 nm was to a large extent (> 85%) present in solution (10^{-2} M HEPES, 10^{-5} M Ca, pH 7.0) after 24 h of
exposure. This is higher than the extent of dissolution we found in our study. However, another study reported that the percentages of ZnONP$_{\text{ion}}$ were only 30% at 0.5 mg/L of ZnONPs and 20% at 2 mg/L of ZnONPs after 24 h of exposure in simplified M7 medium (Li et al., 2013). This discrepancy is a reflection of the combined effects exerted by the characteristics of NPs and exposure medium, such as, ionic strength and pH of the test medium (Li et al., 2013), presence of coatings (Merdzan et al., 2014), and particle size (Meulenkamp et al., 1998). The ion-release profiles of NPs should thus be analyzed on a case-by-case basis. At the high concentration applied in this study (10 mg/L), the percentages of CuNP$_{\text{ion}}$ and ZnONP$_{\text{ion}}$ were almost constant around 10%, much lower than the percentages of ZnONP$_{\text{ion}}$ and CuNP$_{\text{ion}}$ at the low concentrations (namely 1 mg/L ZnONPs and 0.1 mg/L CuNPs). Similarly, Zhao and Wang (2012) found that at a low concentration of AgNPs (10 µg/L) in SM7 medium, the relative percentage of the dissolved Ag released from AgNPs could be beyond 50%, while at a high concentration of AgNPs (1000 µg/L) the percentage of dissolved Ag remained constant at less than 10%. These results indicate that the concentration of NPs is also an important factor to consider regarding the dissolution characteristics of NPs, since the equilibrium between dissolved and adsorbed ions might potentially play a role. Furthermore, it needs to be noted that, especially at high nanoparticle concentrations, the percentage of NP$_{\text{ion}}$ remains constant during the whole exposure time.

2.4.2 Acute toxicity of CuNPs and ZnONPs

In the present study, CuNPs were found to have a LC50 level (0.093 mg/L), which was over 10 times lower than that of ZnONPs (0.99 mg/L). It is thus obvious that D. magna is much more vulnerable to dispersions of CuNPs than to dispersions of ZnONPs. Previous toxicity assessments of NPs have primarily focused on probing into the effects of different exposure routes, such as the respiratory or gastrointestinal tracts (Chang et al., 2015). Most previous studies did not distinguish between the relative contributions of NP$_{\text{particle}}$ and NP$_{\text{ion}}$ to the overall toxicity induced by NPs, or have simply compared the overall toxicity of metal-based NPs with that of corresponding metal salts. However, metal salts import other types of ionic species into solutions, compared to the NP$_{\text{ion}}$ directly, which may exert effects on acute toxicity through combined effects on physiological characteristics and metal speciation (Lopes et al., 2014). In this study, to investigate whether using metal salts to replace NP$_{\text{ion}}$ is effective, comparison of acute toxicity between freshly prepared CuNP$_{\text{ion}}$ and ZnONP$_{\text{ion}}$, and the corresponding metal salts was conducted, respectively. Similar LC50 values of the CuNP$_{\text{ion}}$ and Cu(NO$_3$)$_2$ and of the ZnONP$_{\text{ion}}$ and Zn(NO$_3$)$_2$ were obtained. Our results indicate that using Cu(NO$_3$)$_2$ and Zn(NO$_3$)$_2$ to substitute for CuNP$_{\text{ion}}$ and ZnONP$_{\text{ion}}$ is effective. Furthermore, the results of assessment of the relative contribution to mortality revealed that the CuNP$_{\text{ion}}$ and ZnONP$_{\text{ion}}$, were not the major source of acute toxicity of CuNPs and ZnONPs. Similarly, Li and Wang (2013) also concluded that the toxicity of ZnONPs to D. magna cannot only be attributed to the ZnONP$_{\text{ion}}$ and Santo et al. (2014) even found that the ZnONP$_{\text{ion}}$ did not make any contribution to the toxicity of ZnONPs to D. magna. However, there are also studies which attributed the toxicity of metal-based or metaloxide-based NPs to the NP$_{\text{ion}}$. For instance, Adam et al. (2014a) concluded that the toxicity of ZnONPs to D. magna can be largely attributed to the NP$_{\text{ion}}$ rather than the NP$_{\text{particle}}$; Jo et al. (2012) reported that the dissolved Cu released from CuONPs largely
contributed to the observed acute toxicity to *D. magna*. The different characteristics of NPs and exposure conditions, such as the size of NPs (Lopes et al., 2014) or the pH value of the exposure medium (Bian et al., 2011), may lead to the apparent discrepancy. Thus, more toxicity tests involving a wider range of NPs, exposure conditions, and model organisms, should be conducted in the future. Thereupon, a more explicit description of the test condition is needed.

### 2.4.3 Accumulation characteristics of CuNPs and ZnONPs

While the mechanisms underlying the CuNPs and ZnONPs mediated toxicity in *D. magna* are poorly known, a significant accumulation of CuNPs and ZnONPs in daphnids was observed in this study. The concentrations of Cu and Zn detected in daphnids were quite high (up to 0.1%). These findings are similar to but lower than the maximum body burdens observed for uptake studies with *D. magna* for carbon nanotubes (6.8%, Petersen et al., 2009), fullerenes (0.7%, Pakarinen et al., 2013) and graphene (0.7%, Guo et al., 2013). Furthermore, the accumulation results display that the internal concentrations of Cu and Zn were proportional to the concentrations of CuNPs and ZnONPs administered in this study (Figure 2.4). Actually *D. magna* are filter feeders, enabling them to ingest particles smaller than the size of 70 µm (Geller and Müller, 1981). In our study, both CuNPs and ZnONPs aggregates were far smaller than 70 µm (median particle size about 1 µm), thus they could be readily taken up by daphnids. On the other hand, the aggregation of CuNPs and ZnONPs to approximately 1 µm makes sedimentation likely. There is evidence that sediment particles are ingested by daphnids (Petersen et al., 2009; Lee et al., 2012), but the accumulating rate might be different to suspended particles (Tervonen et al., 2010), and furthermore the adsorption to daphnids’ carapace and appendages might also be different to dispersions if the particles are applied as large aggregates and agglomerates (Lee et al., 2012). Therefore also the size of NPs’ aggregates might be of importance in the accumulation study. At the high concentration of nanoparticle suspensions applied, both CuNP_{(ion)} and ZnONP_{(ion)} contributed only to a limited extent to the accumulation of Cu and Zn, respectively (Figure 2.4). These results indicate that NP_{(particle)} play a dominant role in the accumulation process at the high concentration of CuNPs and ZnONPs, in line with the conclusion obtained from the toxicity assessment of the NP_{(particle)} exposed to neonates. This dominant role of NP_{(particle)} in accumulation process might be reflected in the following manifestations. *D. magna* ingested metals in the particle form more than in the ion form in this study; NP_{(particle)} existing in nanoparticle suspensions may facilitate the intake of NP_{(ion)} by adsorbing metal ions on their surface areas (Tan et al., 2012); it also might be that NP_{(particle)} became predominately packed in organism gut tract; there was adsorption of NP_{(particle)} to the outer shell of daphnids partly; finally, all the above manifestations could coexist. However, which manifestation is the major reason that results in the leading role of NP_{(particle)} requires further research. At the low concentration of the nanoparticle suspensions applied in this study (namely 0.05 mg/L CuNPs and 0.5 mg/L of ZnONPs), both the relative contributions to accumulation of CuNP_{(ion)} and ZnONP_{(ion)} increased to around 50% (Table 2.3). The different contribution to accumulation of NP_{(ion)} might be caused by the different dissolubility of NPs. At a low particle concentration, the proportion of dissolved NPs tends to be higher, whereas it tends to be lower at a high particle concentration (Hua et al., 2014a and 2014b; Mwaanga et al., 2014). Thus, a higher proportion
of NP\textsubscript{ion} might be ingested by organisms at a lower concentration of NPs than at a higher concentration of NPs. Consequently, when the concentrations of CuNPs and ZnONPs were below 0.05 mg/L and 0.5 mg/L, respectively, NP\textsubscript{ion} were predominantly accumulated. The results indicate that at a low concentration of nanoparticle suspensions, ions released from metallic nanoparticles like Cu and ZnO are overshadowing the effects of NPs.

2.5 Environmental implications
This study investigated the potential environmental effects of CuNPs and ZnONPs and their corresponding dissolved ions. Our results demonstrate that at the LC50 levels of CuNPs and ZnONPs suspensions, the NP\textsubscript{particle} dominated the toxicity rather than the NP\textsubscript{ion}. Additionally, at the low exposure concentrations of CuNPs and ZnONPs (below 0.05 mg/L of CuNPs and 0.5 mg/L of ZnONPs, respectively) the NP\textsubscript{ion} was predominantly accumulated, whereas at the high exposure concentration (above 0.1 mg/L of CuNPs and 1 mg/L of ZnONPs, respectively), NP\textsubscript{particle} not only played a dominant role in the accumulation process, but it was also the species primarily responsible for toxicity.

Supplementary information

Supplementary information 2.1
To analyze whether there were still NP\textsubscript{(particle)} remaining in the supernatants after centrifugation, we firstly conducted an ultracentrifugation experiment. Specifically, ultracentrifugation of nanoparticle suspensions was performed at 192700 g for 30 min at 4 °C (Kontron Centrikon T-2070, TFT 50.38 rotor). Subsequently, the dissolved ion concentration in the supernatants prepared by the two methods of centrifugation was compared. If there was no significant difference of dissolved ion concentration in the supernatants obtained by regular centrifugation and ultracentrifugation, it was to be concluded that regular centrifugation can be applied in this study and NP\textsubscript{(particle)} may be completely removed in the supernatant after centrifugation, on the other hand if there was a significant difference, indeed NP\textsubscript{(particle)} would be remaining in the supernatants after regular centrifugation and ultracentrifugation should replace regular centrifugation to be employed in this study. After comparing, it was found that there was no significant difference between the ion concentration in the supernatants disposed by the two different centrifugation methods (Figure S2.1), which means that the supernatants obtained by centrifugation at around 30000 g and subsequent filtration through a syringe filter with 0.02 µm pore diameter, may only contain NP\textsubscript{(ion)}. Furthermore, besides comparing the ion concentration by means of ICP-OES in the supernatants after regular centrifugation and ultracentrifugation, DLS was used to confirm NP\textsubscript{(particle)} were removed in the supernatants after filtration. From Figure S2.2, it is clear that the particle profile of the cultural media (STM) was similar to the profiles of the supernatants of CuNPs and ZnONPs. Moreover, the polydispersity indexes (PDI) of the supernatants of the STM, CuNPs and ZnONPs were very high (higher than the recommended PDI values for the DLS measurement: 0-0.7) and the count rates of them were very low (lower than the recommended count rates for the DLS measurement: 100-500 kcps), which did not meet the quality criteria of the DLS test. These results indicate that the particle concentration in the supernatants obtained by centrifugation at around 30000 g and subsequent filtration through a syringe filter with 0.02 µm pore diameter was less than the combined detection limit of the ICP-OES and DLS of 0.01 mg/L.
Figure S2.1 The comparison of the ion release profiles in the supernatants obtained by regular centrifugation for 30 min at 4 °C with 30392 g and ultracentrifugation for 30 min at 4 °C with 192700 g, respectively. The left graph exhibits the relative percentage of dissolved Cu released from the CuNPs at the concentration of 0.1 mg/L and the right graph displays the relative percentage of dissolved Zn released from the ZnONPs at the concentration of 1 mg/L. Results are expressed as mean ± SD (n = 3).
Figure S2.2 Dynamic light scattering data for particle profiles of the supernatants of STM, CuNPs and ZnONPs. As control, the particle profile of the supernatant of the cultural media (STM) obtained by centrifugation at 30392 g and subsequent filtration through a syringe filter with 0.02 µm pore diameter has been measured first, which was shown in the figure with red line. Then the particle profiles of the supernatants of CuNPs and ZnONPs also obtained by centrifugation at 30392 g and subsequent filtration through a syringe filter with 0.02 µm pore diameter were represented by blue and green lines, respectively.

Supplementary information 2.2
During the procedures of centrifugation and filtration, NPs and NP$_{(ion)}$ may be adsorbed to the sidewalls of centrifuge tubes or on the filter membrane. To analyze the losses of NPs and NP$_{(ion)}$ after centrifugation and filtration, experiments were conducted. Specifically, freshly prepared nanoparticle suspensions were sampled and the nanoparticle concentration in the samples was detected by ICP-OES after digestion in 65% HNO$_3$ for at least 1 day. Moreover, to compare the difference of nanoparticle concentration before and after centrifugation, the nanoparticle concentration after centrifugation at 30392 g for 30 min at 4 °C was also tested by ICP-OES after digestion in 65% HNO$_3$. The difference of NP$_{(ion)}$ concentration before and after filtration was also detected. After centrifugation at 30392 g for 30 min at 4 °C, Concentration of NP$_{(ion)}$ in the supernatant was detected by ICP-OES. Furthermore, supernatants obtained by centrifugation at 30392 g for 30 min at 4 °C were filtered through a syringe filter with 0.02 µm pore diameter (Antop 25, Whatman). Subsequently, the concentration of NP$_{(ion)}$ in the supernatants obtained by centrifugation and subsequent filtration through a syringe filter with 0.02 µm pore diameter was tested. The results were shown in Figure S2.3. It reported that there indeed exist decrease of nanoparticle
Toxicity and accumulation of Cu and ZnO nanoparticles in Daphnia magna

centration after centrifugation and decrease of dissolved ion concentration after filtration. However, the difference of the ZnONPs concentration before and after centrifugation and of the dissolved Zn concentration before and after filtration, as well as of the CuNPs concentration before and after centrifugation and of the dissolved Cu concentration before and after filtration was not significantly different ($p > 0.05$, the $p$-value between different groups was tested by mean of the $t$-test).

Figure S2.3 The losses of NPs and NP$_{\text{ion}}$ after centrifugation and filtration. The left graph shows the concentration of ZnONPs at 1 mg/L before and after centrifugation and the concentration of dissolved Zn released from ZnONPs at 1 mg/L before and after filtration. The right graph exhibits the concentration of CuNPs at 0.1 mg/L before and after centrifugation and the concentration of dissolved Cu released from CuNPs at 0.1 mg/L before and after filtration. Results are expressed as mean ± SD ($n = 3$).
