Abstract

Following abiotic stress to induce barley (*Hordeum vulgare* L.) androgenesis, the development of 794 enlarged microspores in culture was monitored by time-lapse tracking. In total, 11% of the microspores tracked developed into embryo-like structures (type-I pathway), 36% formed multicellular structures (type-II pathway) and 53% of the microspores followed gametophytic divisions, accumulated starch and died in the first days of tracking (type-III pathway). Despite the microspore fate, enlarged microspores showed similar morphologies directly after stress treatment. Ultrastructural analysis, however, revealed two morphologically distinct cell types. Cells with a thin intine layer and an undifferentiated cytoplasm after stress treatment were associated with type-I and type-II pathways, whereas the presence of differentiated amyloplasts and a thick intine layer were associated with the type-III pathway. Tracking revealed that the first morphological change associated with embryogenic potential was a star-like morphology, which was a transitory stage between uninucleate vacuolated microspores after stress and the initiation of cell division. The difference between type-I and type-II pathways was observed during the time they displayed the star-like morphology. During the transition phase, embryo-like structures in the type-I pathway were always released out of the exine wall at the opposite side of the pollen germ pore, whereas in the type-II pathway multicellular structures were unable to break the exine and to release embryo-like structures. Moreover, by combining viability studies with cell tracking, we show that release of embryo-like structures was preceded by a decrease in viability of the cells positioned at the site of exine wall rupture. These cells were also positively stained by Sytox orange, a cell death indicator. Thereby, we demonstrate, for the first time, that a position-determined cell death process marks the transition from a multicellular structure into an embryo-like structure during barley androgenesis.

Introduction

During androgenesis, haploid microspores initially determined to form gametes are reprogrammed to divide and to form embryos, which develop similarly to their somatic and zygotic counterparts (Mordhorst et al., 1997). As a result of frequent chromosome doubling, microspore-derived embryos develop into double haploid plants, providing advantages for both fundamental and applied research (Wang et al., 2000). Since it was first described in *in vitro*-cultured anthers of *Datura innoxia* by Guha and Maheshwari (1964), improvement of the conditions for androgenesis induction and
microspore culture have resulted in the regeneration of double haploids of many plant species (Reynolds, 1997). Due to the high regeneration efficiencies, rapeseed (Brassica napus L.), tobacco (Nicotiana spp), wheat (Triticum aestivum L.) and barley (Hordeum vulgare L.) are considered model systems for androgenesis studies (Touraev et al., 1997). These species offer the possibility for the identification of the genes involved in androgenesis induction and for the development of molecular markers. However, only a few marker genes have been identified so far. Among these, members of the family of heat-shock proteins, napin seed storage proteins and the BABY BOOM gene have been shown to correlate with Brassica androgenesis initiation (Smykal and Pechan, 2000; Boutilier et al., 1994; 2000).

One of the most pertinent problems in the search for suitable molecular markers for microspore embryogenic competence is the heterogeneity of stressed microspore populations, which are composed of embryogenic and non-embryogenic cells (Pechan and Smykal, 2001). Therefore, the identification and isolation of the competent microspores following stress treatment is of great importance. Time-lapse tracking offers the possibility to follow the developmental pathway from single cells to embryos in detail (Krens et al., 1998). This technique has been employed in the identification of morphological traits for the induction of embryogenesis in many plant cell cultures, such as barley and tobacco protoplasts, single suspension cells of carrot (Daucus carota L.), leaf explants from Dactylis glomerata L. and pro-embryogenic masses of Norway spruce (Picea abies L. Karst; Golds et al., 1992; Toonen et al., 1994; Somleva et al., 2000; Filonova et al., 2000a). The identification of cells competent to form embryos in carrot somatic embryogenesis has helped the development of robust embryogenic marker genes, such as the SOMATIC EMBRYOGENESIS RECEPTOR-LIKE KINASE (SERK) and the EP2 gene, which encodes a lipid-transfer protein (Schmidt et al., 1997; Sterk et al., 1991).

In the field of androgenesis, an efficient system of tracking heat-stressed wheat microspores to the embryo stage has been developed by Indrianto et al. (2001), whose findings indicate that a star-like morphology is correlated with embryogenic competence. Single-cell tracking of barley microspores following cold or heat stress to induce androgenesis revealed that only enlarged microspores with a rich cytoplasm and granular appearance were able to develop into embryos (Bolik and Koop, 1991; Kumlehn and Lörz, 1999). So far, the highest regeneration efficiencies from barley microspores have been obtained by the incubation of anthers containing uninucleate microspores in mannitol solution for 4 days at 25°C. After stress treatment, an average of 20–60% of the microspores appear as enlarged, highly vacuolated cells, an indication of embryogenic potential acquirement (Hoekstra et al., 1992). However, only 7% of these enlarged microspores have been reported to develop into embryo-like structures (Maraschin et al., 2003). In order to gain more
information on the morphology of the enlarged cells that ultimately contribute to embryo formation during barley androgenesis following mannitol and starvation treatment, ultrastructural studies and time-lapse tracking of isolated enlarged microspores immobilized in a thin layer of agarose were carried out. Time-lapse tracking was coupled to viability studies, and the successive developmental stages from single barley microspores to embryos were determined, resulting in the elaboration of a fate map of barley microspore embryogenesis. We demonstrate that the star-like morphology indicates a developmental process, and its time of occurrence is associated with the embryogenic potential of barley microspores. Moreover, we report, for the first time, that the transition from a multicellular structure to an embryo-like structure is accompanied by cell death.

Materials and methods

Androgenesis induction, microspore culture and time-lapse tracking

Donor plants of barley (*Hordeum vulgare* L. cv Igri, Landbouw Bureau Wiersum, The Netherlands) were grown in a phytotron under conditions described previously (Hoekstra et al., 1992). Pre-treatment consisted of incubation of anthers containing mid-late to late uninucleate microspores in 0.37 M mannitol solution for 4 days in the dark, at 25°C (Hoekstra et al. 1992). After pre-treatment, microspores were isolated by gentle blending in 0.37 M mannitol solution for 30 s using a commercial blender at medium power (Waring), filtered through 110 µm nylon meshes and collected by centrifugation at 800 rpm for 5 min. The number of enlarged and non-enlarged microspores was estimated in a population of 300 cells in three independent experiments (*n*=3). The enlarged microspores were separated from the non-enlarged ones by a sucrose gradient (Maraschin et al. 2003). The enlarged microspores were plated in medium I (Hoekstra et al., 1992) at a density of 2.10⁴ enlarged microspores per ml, and cultured for 7 days (Hoekstra et al., 1993) for viability studies of multicellular structures (MCSs) or immobilized for time-lapse tracking. Microspores were immobilized onto sterilized 500 µm nylon meshes in 8-well Lab-Tek II chambers (Nalgene Nunc International). For immobilization, each well held 200 µl of medium I (Hoekstra et al., 1992) containing 0.6% (w/v) of low-melting-type agarose (Hispanagar) and 2.10⁴ enlarged microspores per ml. The thin layer of immobilized microspores was covered by 500 µl of medium I per well and the cultures were incubated at 25°C in the dark for 28 days for embryo development. After 1 week of culture, 250 µl of fresh medium I was added to each well. Fluorescein diacetate (FDA; Sigma) was used to assay MCS viability during cell tracking. FDA was used at a final concentration of 1.10⁻⁴ g.ml⁻¹ and was added at day 0 of tracked cultures. The development
of 794 enlarged microspores was followed in three independent experiments \((n=3)\). The immobilized microspores were observed using an inverted Olympus microscope coupled to a Nikon DXM 1200 digital camera. The position of each microspore was determined using the nylon mesh as a reference guide. Digital images were generated at days 0, 1, 2, 3, 4, 6, 8, 10, 14, 16 and 28 of culture using both light and fluorescence microscopy. The microspores were characterized into different types according to their developmental pathways. After 28 days of culture, embryos ranging from 0.5 to 1 mm were transferred to regeneration medium (Hoekstra et al., 1992).

**Transmission electron microscopy**

Enlarged microspores after stress treatment were assayed for ultrastructural studies. Microspores were fixed in a mixture of 2 % (w/v) glutaraldehyde and 2.5 % (w/v) paraformaldehyde in 0.1 M sodium cacodylate buffer, pH 7.3 for 3 h at room temperature. Microspores were immobilized in 1 % (w/v) low-melting type agarose (Hispanagar) and the resulting pellets were returned to fixative solution overnight at 4 °C. Pellets were washed 10 min in 0.1 M sodium cacodylate buffer, pH 7.3, and placed in 1 % (w/v) OsO\(_4\) in 0.1 M sodium cacodylate buffer, pH 7.3 for 1 h at room temperature. Following post-fixation, pellets were washed 10 min in 0.1 M sodium cacodylate buffer, pH 7.3, and dehydrated at room temperature through a graded ethanol series as follows: 70 %, 80 %, 90 %, 96 %, 100 % (v/v). After dehydration, pellets were placed in propylene oxide for 30 min. The resin was infiltrated by incubation in 1:1 (v:v) mixture of propylene oxide:Epon (Agar Scientific) for 2 h, followed by incubation in Epon overnight at room temperature. Embedding was in Epon and polymerization took place at 55 °C for 48 h. Ultrathin sections were made using an ultramicrotome (Ultracut, Leica), stained for 10 min in 2 % (w/v) uranyl acetate in 50 % (w/v) ethanol and for 10 min in 0.4 % (w/v) lead citrate, followed by thorough washes in deionized filtered water. Electron micrographs were made using a Jeol 100 CX electron microscope. Pictures were taken at 60 kV on a Kodak 5302 FGP-film.

**Cell viability and cell death staining of MCSs**

MCSs at day 7 of liquid cultures were stained for cell death with 1 µM of Sytox orange (Molecular Probes) and for cell viability with \(4.10^{-2} \mu g/ml\) of FDA. MCSs were observed using a Leica DM IRBE confocal microscope. An argon and a krypton laser were used for visualization of the FDA and the Sytox orange signal, respectively.
Experimental data

Mean values ± SD of the different developmental pathways were calculated as percentages of the relative frequency of each pathway identified. Significance of the differences in mean values was tested with a Student’s t-test.

Results

Stress-induced developmental pathways identified by time-lapse tracking

Following mannitol and starvation stress, 51.6±4.8% \((n=3)\) of the isolated microspores were composed of enlarged, vacuolated cells with yellow/red interference of the exine wall. These enlarged cells were cultured in a thin layer of agarose for development of embryo-like structures (ELSs). The fate of 794 enlarged cells was followed by time-lapse tracking in three independent experiments \((n=3)\). Developmental stages were observed at different time-points and the microspores were characterized according to their developmental pathways. This system yielded 10.9±4.2% ELSs released out of the exine wall. These ELSs were capable of regenerating into a new plantlet when transferred to germination medium (data not shown). When enlarged microspores are cultured at the same density in liquid medium, 7% of the microspores develop into ELSs (Maraschin et al., 2003). This suggests that the immobilized cultures are comparable to the liquid system.

Mainly three types of developmental pathway were identified (Fig. 1). Developmental type I, or the embryogenic pathway, represented 10.9±4.2% of the microspores tracked. This group comprised the microspores that followed sporophytic cell divisions, formed multicellular structures (MCSs) and were capable of releasing ELSs out of the exine wall of microspores (Fig. 1a–e). MCSs ruptured the exine wall of microspores after 10.5±1.1 days of cell tracking (Fig. 1e). In the liquid culture system, MCSs usually rupture the exine wall of microspores after 7–8 days of culture (van Bergen et al., 1999), thus immobilized cultures display a 2- to 3-day delay compared to liquid ones. Developmental type II (36.2±2.4%) was also represented by microspores that followed sporophytic cell divisions, formed MCSs but showed shrinkage of the whole structure and died in an asynchronous way. Death occurred mostly between days 7 and 10 of culture, prior to the time of exine wall rupture in the type-I developmental pathway (Fig. 1f-j). Eventually, dead material was extruded from the exine wall of these MCSs (Fig. 1j). Microspores grouped into developmental type III (52.9±4.5%) did not display sporophytic divisions and died soon after initiation of culture (Fig. 1k–n). In order to identify the morphological characteristics of embryogenic microspores at an early developmental stage, microspore morphology at day 0
Chapter 2

of tracking from type-I, -II and -III developmental pathways was analyzed. Cells were characterized by the presence of a big central vacuole, surrounded by a narrow strip of cytoplasm in which one nucleus was present. Differences were observed in the nuclear position relative to the pore (0–180°), the exine wall light interference (yellow to red) and in the cytoplasm granularity (Fig. 1a,f,k). However, none of these traits was exclusive to any of the developmental types identified. The first morphological change associated with sporophytic development was nuclear migration towards the middle of the microspore. This phenomenon was observed between days 0 and 3 of tracking in 60% of the microspores following developmental types I and II (Fig. 1a–c, f,g). Central localization of the nucleus was observed concomitantly with fragmentation of the large central vacuole, which was interspersed with centripetally oriented cytoplasmic strands. In both developmental types, the acquisition of a star-like morphology of the cells was always followed by sporophytic divisions. By monitoring the evolution of the star-like morphology over a period of 24 h, it was possible to observe that sporophytic divisions commenced characteristically at the side opposite to the pollen germ pore (Fig. 2a–e). In the first 2 h, the centrally located nucleus migrated towards the side opposite to the pollen germ pore (Fig. 2a–c), followed by nuclear division after 4 h (Fig. 2d). After 24 h, more than half of the space contained by the exine was filled by three visible nuclei (Fig. 2e). However, there seemed to be a difference in the time of appearance of the star-like morphology between developmental types I and II (Fig. 1c,g; Table 1). In developmental type II, 85.4±2.5% of the microspores displayed the star-like morphology in the first 24 h of tracking, whereas only 65.4±4.8% of the microspores following the type-I pathway showed the star-like morphology in the same period (P<0.06). Microspores following developmental type III were never found to display the star-like morphology. In most cases, microspores displayed gametophytic divisions and died soon after initiation of tracking, indicating that these microspores were still committed to the pollen developmental pathway (Fig. 1k-n). A comparison of developmental types I, II and III is shown in Table 1.

Subcellular differences in enlarged microspores after stress treatment

At day 0 of tracking, irrespective of their developmental pathway, enlarged microspores showed similar morphologies at the light-microscopy level (Fig. 1a,f,k). Ultrastructural studies of enlarged cells at day 0 of culture were carried out using transmission electron microscopy (TEM). Based on their cytological characteristics, mainly two types of enlarged microspore could be identified. One type of microspore showed a large nucleus close to the exine wall and a narrow strip of cytoplasm surrounding the vacuole.
Figure 1. Developmental pathways of stressed enlarged barley microspores in culture, as determined by time-lapse tracking. According to their type of development, microspores were grouped into type I (a–e); type II (f–j) and type III (k–n). Arrowheads in (a), (f) and (k) indicate the position of the nucleus in relation to the pollen germ pore: 0°, 0° and 90–180°, respectively. Each developmental type is summarized in Table 1.

Figure 2. Evolution of a star-like morphology in developmental type I barley microspores, as monitored over a period of 24 h. The star-like morphology was observed from 1 to 2 days of culture by phase contrast. Images were taken every hour from several star-like structures, and representative examples are shown. cs cytoplasmic strands, n nucleus, p germ pore, v vacuole.
The intine was present as a thin layer immediately underneath the exine wall (Fig. 3a–c). In another type of vacuolated microspore with the nucleus close to the exine wall, an organelle-rich cytoplasm, filled with differentiated amyloplasts, and a thick intine layer were present (Fig. 3d–f). Amyloplasts containing starch granules were often associated with microspores with a thick intine layer (Fig. 3d–f), but were never found in microspores that had a thin intine layer (Fig. 3a–c). In the latter, only a few organelles were present, such as rough endoplasmic reticulum, mitochondria and undifferentiated proplastids (Fig. 3b,c).

When mid-late to late uninucleate microspores were allowed to further develop in the mother plant for 4 days, they displayed gametophytic cell divisions and developed into binucleate pollen. TEM analysis of these binucleate pollen grains following normal gametophytic development revealed that these cells possess a thick intine layer and an organelle-rich cytoplasm (Fig. 3g–i). The cytoplasm contained numerous mitochondria, Golgi apparatus, rough and smooth endoplasmic reticulum and starch granules in the differentiated amyloplasts (Fig. 3h,i). This cytoplasmic morphology was similar to that observed in the type of enlarged cell with a thick intine layer, indicating that, morphologically, the latter showed signs of gametophytic development (Fig. 3d–f), which, however, was less advanced than for binucleate pollen, as starch granules were much smaller and less numerous.

Table 1. Characterization of developmental types by time-lapse tracking of stressed barley (*Hordeum vulgare*) microspores. The development of 794 enlarged microspores was followed in three independent experiments (n=3). The presence or absence of the characteristic is indicated by + or –, respectively. The percentage of star-like structures in developmental types I and II was calculated with respect to the total number of star-like structures visualized in each developmental pathway.

**Cell viability of developmental type-I and type-II MCSs**

Both developmental types I and II gave rise to MCSs and together accounted for 47.1±4.5% of the tracked microspores, in an estimated ratio of 1:5 (I:II). However, microspores following developmental type II never released ELSs out of the exine wall of microspores, indicating that this is a crucial step in the androgenic process of barley. In order to gain more information on the fate of MCSs following developmental types I and II, viability studies were coupled to time-lapse tracking. To do so, FDA was added to the immobilized cultures and observed until the time of exine wall rupture. The FDA concentration used during tracking did not affect the growth rate or the morphology of the cells, suggesting that this FDA concentration is not toxic for microspore-derived embryo development (data not shown).
Figure 4. Developmental types I (a–m) and II (n–y), as visualized by light microscopy (brightfield; columns I and II) and fluorescence microscopy after staining with FDA (columns I+FDA and II+FDA). Arrowheads in (e) and (f) indicate the point of exine wall rupture, and in (k–m) and (x) indicate an MCS domain with lower intensity of FDA staining. The shadow in (g) corresponds to the mesh used in tracking experiments.
Figure 4 shows representative examples of developmental type I (Fig. 4a–m) and type II (Fig. 4n–y) observed by brightfield and fluorescence microscopy. During the first sporophytic divisions, MCSs following developmental types I and II were evenly stained by FDA, indicating viability of the whole structure (Fig. 4h–j, t–w). However, 2–3 days prior to exine wall rupture in MCSs following developmental type I, some domains were unstained by FDA near the area of exine wall break, opposite to the pollen germ pore (Fig. 4k, arrowhead). In the brightfield image, the FDA-unstained areas displayed further cell shrinkage and dead cell material was released out of the exine wall of microspores (Fig. 4e–f, l–m, arrowheads). In developmental type II, FDA-unstained domains were observed immediately prior to MCS death, about 2–4 days later than observed for MCSs following the type-I developmental pathway (Fig. 4x, arrowhead).

In order to confirm that the areas unstained by FDA represented dead cells within MCSs following the type-I developmental pathway, confocal laser scanning microscopy (CLSM) analysis of Sytox orange in combination with FDA staining was used. Sytox orange is a cell death indicator, which will only stain the nuclei of cells with damaged membranes. These studies were performed in liquid cultures of enlarged microspores due to the impossibility of using CLSM in agarose-immobilized cultures. In this system, exine wall rupture was observed after 7–8 days of culture (van Bergen et al., 1999). Therefore, FDA/Sytox orange analysis in MCSs was performed after 7 days of liquid culture. Figure 5 shows a confocal z-series of a 7 days-old MCS displaying one domain unstained by FDA, at the point of exine wall rupture (Fig. 5a,b, arrowheads). The same domain is positively stained by Sytox orange (Fig. 5c), indicating that the cells surrounding the point of exine wall break are dead.

Figure 5. Brightfield image (a) and CLSM (b,c) of MCSs at the stage of exine wall rupture, stained by FDA and Sytox orange. (a) Exine wall rupture in a 7 days-old MCS grown in liquid culture. The site of exine wall rupture is marked by arrowheads. (b) The same MCS displayed in (a) showing FDA-unstained cells at the point of exine wall rupture (arrowheads). Discussion

Morphology of microspores following androgenesis in barley

Using time-lapse tracking, mainly three developmental pathways were observed and their frequencies quantified: type I, which was the embryogenic pathway (11%); type II, which displayed sporophytic divisions, but failed to make the transition from an MCS into an ELS (36%); and type III, which degenerated in the first days of culture (53%). By tracking back these microspores to day 0 of culture, it was found that no typical morphology was associated with any of the developmental types described. Nevertheless, ultrastructural analysis of enlarged microspores by TEM revealed two distinct types of microspore. One type displayed a thin intine layer and an undifferentiated cytoplasm, while the other showed a thick intine layer and a starch-rich cytoplasm, and thus resembled developing pollen grains. Starch accumulation in the pollen amyloplasts marks the commitment to the pollen developmental pathway (McCormick, 1993). Our observations indicate that the enlarged cells that evolved to pollen morphology after stress treatment were still committed to the gametophytic pathway, probably representing the developmental type III identified by time-lapse tracking. On the other hand, microspores with undifferentiated cytoplasm have been associated with the repression of the gametophytic pathway, as reported for induced tobacco, rapeseed and wheat microspores (Rashid et al., 1982; Telmer et al., 1995; Indrianto et al., 2001). Prior to induction of androgenesis, barley uninucleate microspores are characterized by the lack of specialized morphological structures in the cytoplasm and a thin intine layer (Huang, 1986). This suggests that, in barley, the microspores with undifferentiated cytoplasm and a thin intine layer after stress treatment are probably associated with the repression of the gametophytic pathway (developmental types I and II). The maintenance of a thin intine layer after stress treatment may represent an early morphological marker for induced microspores in barley.

Tracking showed that the first developmental change associated with dividing microspores (developmental types I and II) was a star-like morphology, which was characterized as a transitory stage between vacuolated microspores after stress treatment and the initiation of cell division. The occurrence of a star-like morphology appears to be correlated with embryogenic potential in other androgenic systems, such as tobacco, wheat and rapeseed (Zaki and Dickinson, 1991; Touraev et al., 1997). Though very well documented, the cellular and molecular mechanisms implicated in the central positioning of the microspore nucleus prior to its divisions are not yet clear. Increasing evidence indicates that actin filament rearrangements play a role in the division symmetry (Gervais et al., 2000) and the presence of microtubule preprophase bands was shown to be important to the
symmetrical division of heat-shocked rapeseed microspores following central localization of the nucleus (Simmonds and Keller, 1999). Though the symmetry of the first division could not be verified in this study, subsequent divisions following the star-like morphology were shown to occur at the side opposite to the pollen germ pore, at the site where the generative cell is located during normal pollen development. At the stage when the dividing cells started to fill the exine cavity, they resembled very much the morphology of the cytoplasm-rich microspores previously identified by single-cell tracking as being embryogenic (Bolik and Koop, 1991; Kumlehn and Lörrz, 1999).

Although the star-like morphology appears to be a morphological marker for the initiation of cell division in stressed microspores, a star-like morphology per se does not assure that a microspore will ultimately commit to the embryogenic pathway. According to Indrianto et al. (2001), the occurrence of a star-like morphology is a dynamic process, in which the time of occurrence will depend on the type of stress applied and the stage of microspore development. In barley, microspores of developmental type I displayed the tendency to form a star-like morphology relatively later than type-II microspores. Our results indicate that the different microspore developmental pathways may reflect differences in the microspore developmental stage during the period of stress treatment.

**Transition from MCSs to ELSs during androgenesis in barley**

One of the main events that distinguishes androgenesis from other embryogenic systems (zygotic, somatic and apomictic) is the fact that the first divisions of induced microspores are confined by the exine wall (Mordhorst et al., 1997). Therefore, during androgenesis, embryo development relies upon rupture of the exine wall that surrounds the dividing cells. We have demonstrated that 47% of the microspores tracked were induced to divide and to form MCSs (developmental types I and II). However, only MCSs following the type-I developmental pathway were successful in making the transition from an MCS to an ELS, while MCSs from the type-II developmental pathway degenerated and died. These results indicate that successful embryo formation during androgenesis might be a two-step process. The first step would be the induction of cell divisions in those microspores that have acquired the star-like morphology after stress treatment (developmental pathways I and II). Successful ELS release out of the exine wall and further embryo formation would represent a second step that would involve the perception of other, as yet unknown, developmental cues.

It is known that barley microspore embryos can progressively secrete glycosylated proteins and arabinogalactan-proteins in the course of culture, which allow the development of maize immature zygotic embryos in vitro (Paire et al., 2003). Though little is known about the mode of action of these secreted molecules in microspore embryo formation, these findings indicate...
that stress alone does not support the embryogenic route and reinforce the idea that a second trigger might be involved. The question raised is whether developmental type II can be shifted into type I by manipulating the stress and/or culture conditions. Plant regeneration has been reported to increase as a result of application of abscisic acid during pre-treatment and by the use of ovary co-culture in low-response barley cultivars, though that seems not to be the case in the highly responsive cv. Igri (van Bergen et al., 1999; Li and Devaux, 2001). In terms of breeding, it will be a challenge to determine which conditions need to be optimized in order to favor type-I development.

During androgenesis, the process of exine wall rupture has been widely accepted as a passive event that occurs by mechanical rupture due to the growing size of the dividing cells during the transition from MCSs to ELSs (Raghavan, 1986). By time-lapse tracking, we have observed that exine wall rupture always occurs at the side opposite to the pollen germ pore. In wheat, exine wall rupture has been reported to occur opposite to the site of starch granule accumulation (Indrianto et al., 2001). MCSs from monocots such as barley, maize and wheat are known to possess two domains with different cellular organizations (Sunderland and Huang, 1985; Huang, 1986; Bonet and Omedilla, 2000; Magnard et al., 2000; Ramírez et al., 2001; Testillano et al., 2002). In contrast, the divisions that take place inside the exine wall appear to be random in rapeseed microspores and no defined site of exine wall rupture has been reported (Telmer et al., 1995; Yeung et al., 1996). The highly organized structure of microspore-derived MCSs from monocots and the reports of a defined site for exine wall rupture indicate that exine rupture might be a controlled process rather than a passive event.

Further evidence that may support this idea is the finding that the cells on the side opposite to the pollen germ pore die prior to exine wall rupture. During androgenesis, the death of specific cell types has been described within microspore-derived MCSs from many plant species. Depending on the type of developmental pathway, the vegetative or the generative nucleus divides and the undivided nucleus degenerates and dies, a process that envisages the elimination of undesired cells (Raghavan, 1986). Barley MCSs are known to have diverse origins, and both vegetative and generative cell origins have been reported (Sunderland et al., 1979). Though the vegetative or generative origin of the dying cells on the side opposite to the pollen germ pore is not yet known, the side opposite to the pollen germ pore is where the generative nucleus is positioned after the first pollen mitosis during normal pollen development (Huang, 1986). This suggests that this may be a position-determined cell death. Clear examples of position-determined cell death are found during xylem formation (Bhalerao and Bennett, 2003) and during both female gametophyte development and fertilization. During megasporogenesis, only the chalazal-most megaspore survives while the
other three undergo cell death (Drews et al., 1998), whereas during fertilization only the synergid that is located on the side close to the placenta where pollen tubes turn into the ovule degenerates (Wu and Cheung, 2000). In both cases, cell death has been shown to present features of programmed cell death (PCD), a genetically regulated process that occurs upon plant development both in vivo and in vitro and responds to positional and temporal cues (Wu and Cheung, 2000). Developmental uses of PCD comprise a wide range of purposes, mostly associated with shape remodeling of the plant body plan (Pennell and Lamb, 1997). During in vitro somatic embryogenesis in Norway spruce, PCD takes place during the transition phase from pro-embryogenic mass to somatic embryo (Filonova et al., 2000b) and has recently been demonstrated to be essential for correct embryo pattern formation (Bozhkov et al., 2004). In our system, successful embryogenesis relied on position-determined cell death, which preceded the release of ELSs out of the exine wall of MCSs. Our immediate aim will be to investigate whether PCD is involved in the execution of exine wall rupture and further embryogenic development during barley androgenesis.

Acknowledgements

We are grateful to Sandra van Bergen (TNO Department of Applied Plant Sciences, The Netherlands) for technical assistance and valuable discussion and Dr. Wessel de Priester (Institute of Biology Leiden, Leiden University, The Netherlands) for critical reading of the manuscript.
